

## Preliminary preface to NMSOP-2

Ten years have passed since the first printed edition of the IASPEI New Manual of Seismological Observatory Practice (NMSOP 2002). Some 2,000 hard copies are currently in use in more than 100 countries at seismological observatories, data and analysis centers, in teaching, research, and field applications, national and international seismology training courses, or by private enterprises and individual scientists. In 2006, Seismological Press Beijing published a two-volume hard cover edition in Chinese. In 2010 the Badan Meteorologi Klimatologi dan Geofisika (BMKG) in Jakarta, with support of the Japan International Cooperation Agency (JICA), published the first 3 Chapters of NMSOP in (Bahasa) Indonesian language. Three more Chapters are currently being translated and scheduled for publication in 2012. The first four Chapters have been translated into Turkish, with more being in preparation, and Russian translations of several NMSOP Chapters are used at seismological observatories and analysis centers in Russia and other countries of the Commonwealth of Independent States (CIS) already since 2006.

Such global adaptation and use, signals a growing demand for the kind of information provided by the NMSOP and time for a rigorous update. NMSOP-2 will be published as a pure electronic edition. It is again the result of a great cooperative international effort: 73 authors from 18 countries have contributed to (or are still working on) it. More than 70 experts from 20 countries provided peer reviews, and Dr. Siegfried Wendt, himself author and co-author of several contributions to this Manual, has compiled a long-period filtered teleseismic broadband record section of the Collm (CLL) observatory in Germany, which now embellishes the front cover page of NMSOP-2. In this spirit, with this aim, the NMSOP needs to be maintained and further developed under the auspices of IASPEI and its Commission on Seismological Observation and Interpretation (CoSOI). Only then is it assured that the seismological community can always refer to an up-to-date and IASPEI-authorized guidance in observatory practice in the widest sense of modern applications.

The electronic version of NMSOP-2 will be realized in several steps during 2012, as manuscripts become available after completed review, revision and editing. Future revisions of NMSOP will have to adopt this approach of piece-wise realization anyway. An overall revision of such a huge and topically complex publication within a fixed time frame and in mostly voluntary work is no longer feasible and practicable, and the current editor will no longer be available for it. Therefore, anyone who wishes to propose further improvements or new topics or to make such a contribution himself is highly welcome and should contact the editor Torsten Dahm ([torsten.dahm@gfz-potsdam.de](mailto:torsten.dahm@gfz-potsdam.de)) and/or the CoSOI chairman, Dr. Dmitry Storchak, Director of the ISC ([dmitry@isc.ac.uk](mailto:dmitry@isc.ac.uk)).

NMSOP-2 and future follow-up versions will be freely accessible and downloadable. The newly chosen format (see *Editorial Remarks*) permits easy upgrading and complementing of NMSOP in accordance with rapid developments and changing requirements. It also minimizes the need for an overall editorship by emphasizing personal initiative and responsibility of all NMSOP authors, both current and future ones, for their contributions under the auspices of CoSOI/IASPEI and ISC. Thus, the IASPEI New Manual of Seismological Observatory Practice now becomes a **truly dynamic publication**.

NMSOP-2 provides access and download options for many valuable computer programs on:

- Event location
- Ray tracing
- Seismogram analysis
- Parameter determination
- Instrument calibration
- Record filtering
- Fourier analysis
- Network modeling

Moreover, we have complemented several topical contributions and exercises by animations (movies). They can be activated or downloaded (as the programs) from the listing *Download programs and files* (see overview on the NMSOP-2 cover page). These movies illustrate striking features, such as:

- Ray propagation of different seismic phases through the Earth interior;
- Great slowness differences of their propagating wavefronts on the Earth surface;
- Formation of related seismic records and travel-time curves in a regional network;
- Dependence of source radiation patterns and directivity on source azimuth, epicentral distance, fault strike, dip angle, and slip direction.

We are strongly interested to expand such new NMSOP features and invite other authors, who have developed similar modules of high educational value, to make them available as complementary material to relevant topics of the electronic NMSOP edition. Proposals should be addressed to the editor Torsten Dahm ([torsten.dahm@gfz-potsdam.de](mailto:torsten.dahm@gfz-potsdam.de)).

### **What necessitated a second edition of the NMSOP?**

Since the first NMSOP edition in 2002 rapid developments have taken place in many fields of observatory seismology, concerning both sensor and data acquisition technologies, the growing automation of data analysis and interpretation, widening applications of seismological technologies and methods in volcano monitoring, rupture tracking, microzonation, hazard assessment, earthquake and tsunami early warning, strong-motion, ocean bottom and engineering seismology as well as other fields. This necessitates upgrading of several existing NMSOP (2002) chapters and auxiliary materials as well as the addition of new ones.

At the 2007 IUGG/IASPEI General Assembly in Perugia, Italy, the Editor proposed to guide the elaboration of a purely electronic, significantly amended version of the NMSOP. CoSOI accepted this initiative and re-established a related NMSOP Working Group. The detailed NMSOP-2 project plan was presented two years later at the 2009 IASPEI General Assembly in Cape Town, South Africa. An essential component in this plan was the commitment of the library of the GFZ German Research Center for Geosciences in Potsdam to host and professionally maintain on a long-term basis the electronic versions of NMSOP. This commitment was demonstrated in the same year by putting the editorially slightly revised and corrected 2002 edition as NMSOP-1 on the Internet and allocating DOI-numbers to all reviewed contributions.

NMSOP-1 will continue to be available on the GFZ website also in future. This assures preserving many valuable older pieces of information which NMSOP-2 will not duplicate but refer to. Since October 2011, all electronic versions of NMSOP have their own, very easy to access website address: <https://nmsop.gfz-potsdam.de/>, which is mirrored on the Websites of

IASPEI (<http://www.iaspei.org/projects/NMSOP.html>) and of the International Seismological Centre (<http://www.isc.ac.uk/standards> ).

We have opted for a web-only edition of NMSOP-2. The reasons are pragmatic and economic: Increased mailing costs for bulky hard copies, out-rating even production cost, would not assure that NMSOP-2 will be affordable for those most in need of it. On the other hand, rather cheap and speedy computer and Internet facilities have meanwhile become available on a global scale, even in most of the earthquake-prone low-income developing countries.

To ease the orientation of users in the current, still incomplete preliminary version of NMSOP-2, we have compiled a complete *List of* (all expected) *NMSOP-2 titles* (see cover page). Already finalized and downloadable items, preliminary versions and those still in the pipeline are marked therein in different color. For more information consult on the cover page *Editorial Remarks* and *Rights\_Permissions\_Acknowledgments\_References\_NMSOP\_2*.

Special thanks go again to Ms. Margaret Adams (UK/USA) for final English proof-reading of all manuscripts of the first edition, and to Ms. J. Suckale, Ms. A. Sachse, Ms. U. Borchert, Ms. R. Milkereit, Mr. Ch. Nerger and Mr. L. Gabrysch for their valuable technical assistance in consistent formatting, drawing of figures and compiling the lists of acronyms, the glossary and the index for the first NMSOP (2002) edition. Although the current Web edition has been significantly amended, much of these early efforts have still been preserved in NMSOP-2. For this 2<sup>nd</sup> edition, however, the undersigned had to accomplish all editorial work alone, without any such technical or clerical support. Therefore, any short-comings in this regard are solely his responsibility. The electronic version makes it now easy to eradicate both errors in substance or annoying typos. Manual users which spot such errors or typos are kindly requested to inform the Editor.

NMSOP authors and NMSOP Working Group members would like to express their gratitude to IASPEI for entrusting this important task to them and for the continuous interest taken and encouragement provided by CoSOI. Particular thanks go to the many external reviewers (see *List of Reviewers*). Their constructive criticism and suggestions have greatly facilitated the completion of this work, helped to improve original drafts and thus to assure high standards of both professionalism and comprehensibility of the texts for the very broad NMSOP user community. More specific acknowledgments are given at the end of individual NMSOP chapters or auxiliary items.

Most important for the implementation and maintenance of NMSOP-2 on the web has been, and will continue to be for years to come, library of the GFZ ([bib@gfz-potsdam.de](mailto:bib@gfz-potsdam.de)). The library team, in close collaboration with the GFZ computer centre, will be the future key point of contact for both the authors and CoSOI in assuring the correct and comfortable long-term representation and upgrading of the IASPEI Manual. The editor has greatly benefitted from his expertise and cooperativeness in developing a suitable concept tuned to the specific potential of the web edition of NMSOP-2 at the GFZ. Gratefully acknowledged in this context is also the financial support granted to the editor by the GFZ in this final phase of completing NMSOP-2.

Peter Bormann (NMSOP Editor)

Potsdam/Kleinmachnow, January 2012

The 2<sup>nd</sup> Edition of the  
IASPEI New Manual of Seismological Observatory Practice  
is dedicated to the

**150<sup>th</sup> birthdays**  
**of the founders of modern observatory seismology**

**Emil WIECHERT (1861-1928)**

- Born on 26.12.1861 in Tilsit
- 1881-89 study of Physics at Königsberg (now Kaliningrad)
- 1896 discovers the electron, determines its ratio mass to electric charge and proposes that the Earth's core consists of iron
- 1898 world-wide first appointment as Professor of Geophysics (Göttingen Univ.)
- 1900 first WIECHERT pendulum seismometer
- 1901 attendance of the International Seismological Conference at Strasbourg, becoming one of the "founding fathers" of the International Association for Seismology, the forerunner of IASPEI
- 1902 opening of the seismological station Göttingen
- 1903 publication of the "Theory of automatic seismographs"
- 1904 17t horizontal pendulum at Göttingen station
- 1910 WIECHERT-HERGLOTZ formulas, allowing the exact analytical solution of the inverse problem for calculating 1D velocity-depth models from continuous prograde travel-time curves.
- Passed away at Göttingen on 19.03.1928
- About 180 WIECHERT seismographs of different type were operated at more than 110 observatories world-wide, some of them still being in use today.

and

Emil Wiechert with one of his vertical component seismographs

**Boris Borisovich GALITZIN (1862-1916)**

- Born on 02.03.1862 in Saint Petersburg
- Study of physics and mathematics at Strasbourg University
- 1893 "Research into the Mathematical Physics" with which he paved the way for the emergence of quantum mechanics
- Since 1894 Director of the Physical Cabinet of the Russian Imperial Academy of Sciences
- 1901 proposes and builds the first vibration table for instrument parameter calibration
- 1902 General theory of the horizontal pendulum; proposes electromagnetic transducer and pendulum damping with galvanometric-photographic recording
- 1907 proposes at the meeting of the International Seismological Association the general introduction of damped pendulums
- Design and testing of a piezoelectric accelerometer
- 1911 first determination of the energy of an earthquake by estimating the energy density from distant seismic recordings
- 1912 publication of his pioneering "*Lectures on Seismometry*"
- 1913 elected as Director of the Main Physical Observatory
- Developed the first program on earthquake prediction research and hypothesized about triggering effects of seismicity
- Detailed study of microseisms for forecasting cyclonic activity
- Galitzin seismometers were used world-wide until mid 1970s
- Passed away on 17.05.1916

## Emil WIECHERT's motto:

(written in 1902 over the entrance to the seismological station Göttingen, Germany)

*The trembling rock  
bears tidings from afar -  
Read the signs!*

## Seismographs and recordings

The 1904 17t WIECHERT pendulum ( $T_s = 2.2$  s, magnification  $\approx 2000$ )

The 1904 WIECHERT astatic horizontal component pendulum (mass = 1.2t,  $T_s \approx 8.5$  s, magnification  $\approx 200$ ) and record of the  
↓ 1906 San Francisco earthquake at Göttingen

## Boris Borisovich Galitzin's seismographs and records

3-component set of electro-dynamic GALITZIN seismographs at Pulkovo station  
(Photo by A. Ya. Sidorin)

Amplification curves (1) of the electrodynamic GALITZIN seismograph with galvanometric recording, (2) of the Rebeur-Paschwitz seismograph, (3) of the Milne seismograph, and (4) of the heavy horizontal GALITZIN pendulum. Note the resonance peaks of the unattenuated seismographs (2) and (3).

Record examples (a-b) of the electrodynamic GALITZIN seismograph, (c-d) of the Rebeur-Paschwitz instrument and (e) of the Milne seismograph.

## **Complementary remark**

The year 2012 is also the 150<sup>th</sup> anniversary of **Radó Kövesligethy (1862-1934)**, the founder of the seismological observatory Budapest (1905) and Secretary General of the International Seismological Association (ISA; 1905-1922). Kövesligethy made several important theoretical and methodological contributions to seismology, amongst them the macroseismic procedure of depth determination of earthquakes and, in 1905 at the Hague conference of the ISA, he proposed the calculation of the emergence angle of seismic rays based on 3-component records. This stimulated B. B. Galtizin to develop his famous vertical-component seismograph. For a detailed account of the work of R. Kövesligethy see on the IASPEI website <http://www.iaspei.org/newsletters/newsletters.html> Peter Vargas contribution to the IASPEI Newsletter of November 2012.

## **Acknowledgments**

The dedication has been compiled by the Editor, P. Bormann, using different sources. The Wiechert portrait photo and the San Francisco earthquake record were copied with kind permission of the University of Göttingen, Germany, and the drawings of the Wiechert pendulums from Galitzin's (1910) publication on seismometry.

The portrait of B. B. Galitzin, of his instruments as well as of the comparative responses and record examples were copied, with kind permission of the authors Alexander Ponomarev and Alexander Sidorin, from a commemorative leaflet prepared on the occasion of the 33rd General Assembly of the European Seismological Commission (ESC), Moscow, 19-24 August 2012. For more details see also the IASPEI Newsletter of October 2012.

The New Manual of Seismological Observatory Practice (NMSOP 2002) was originally published in two printed volumes. Volume 1 comprised 13 topical Chapters, while Volume 2 contained different kinds of complementary annexed material. Annexed to most of the Chapters were Datasheets (DS), Exercises (EX), Information Sheets (IS), Program Descriptions (PD) and under Miscellaneous Acronyms, Glossary, the summary list of References and an Index. The only slightly revised first web edition of the Manual in 2009, thereafter termed NMSOP-1, reproduces the contents and outlook of NMSOP (2002)

Although the second electronic edition NMSOP-2 (2012) keeps the general classification of content and the internal structure of earlier Manual issues, it is no longer subdivided into two volumes. It also no longer requires an *Index* and a summary list of *References*. Powerful electronic search tools make a typed Index obsolete, and the saving of printed pages by avoiding repeated quotations of the same sources in the reference lists of individual papers is also no longer a valid argument for an electronic manual. Any reviewed individual contribution to NMSOP-2 now has its own DOI-number and can be downloaded separately. Therefore, more benefit is seen in considering each Manual contribution as a self-contained publication with its own reference list and the complete addresses of the authors. Accordingly, also the NMSOP (2002) summary *List of Authors* and *List of Contents* have been skipped. Instead, each NMSOP-2 item with more than 10 pages (with the exception of DSs and PDs) is now preceded by its own list of contents with page numbering. This gives readers a quick overview from the outset and eases the targeting of topics of specific interest.

What else is new in NMSOP-2? Four Chapters (14 to 17) and many new complementary materials have been added, including power point presentations, educational animation films and software, which also can be downloaded individually. Most other items of previous editions have been revised and often significantly amended as well. Both new and amended old contributions are recognized by DOI-numbers which contain “NMSOP-2\_...”, in contrast to unchanged earlier contributions. The latter are linked by their DOI-numbers, containing “NMSOP\_r1\_...”, to the only in some items slightly revised NMSOP-1 (2009) edition.

The original numbering of Chapters and complementary materials remains unchanged in NMSOP-2. Each Manual Chapter is broken down into sections and sub-sections, e.g., Chapter 5, Section 5.1, Sub-section 5.1.2, or even further. The first number always relates unambiguously to the respective Chapter. The same applies to the numbering of figures, tables and equations. Also annexed DS, EX, IS, and PD are numbered according to the Chapter to which they refer, followed by a sequence number, e.g., DS 3.1 is the first Data Sheet belonging to Chapter 3 whereas EX 5.4 is the Exercise number 4 related to Chapter 5. All Manual items have thus been linked with each other editorially, easing mutual cross-references, balancing of contents and avoiding unnecessary duplications of issues.

Not numbered, however, are texts and listings that relate to the Manual as a whole, such as *Acronyms*, *Editorial Remarks*, *Glossary*, *Prefaces*, and *Rights\_Permissions\_Acknowledgements\_References*. These files can be opened from the Manual content **Overview** on the NMSOP-2 cover page. The acronyms used in the Manual sometimes relate to institutions, organizations or programs that have their own web site; in those cases, we have added the web addresses in the alphabetical list of *Acronyms*.

The Manual is utilized by a very broad user community, including beginners, high-school students, teachers, disaster managers or specialists from other disciplines, who may not be sufficiently familiar with specific seismological terminology. Therefore, the *Glossary* in this

Manual includes also terms that may be common knowledge to seismologists but require a simple explanation for other users. When compared with the first edition, the *Glossary* in NMSOP-2 has been tremendously expanded by merging and harmonizing the glossaries in NMSOP (Bormann, 2002 and 2009), by Aki and Lee (2003) and by Lee (2009), and by adding additional entries of the editor and several other Manual authors. With nearly 200 pages this is at present the largest-ever published glossary explaining seismology related terms. [Therefore, users who have difficulties to understand some technical terms out of the context should consult the \*Glossary\* for a more comprehensive definition and explanation.](#) Yet, still the editor considers this current version to be a preliminary and maybe forever an open-ended one. Therefore, proposals for further amendments or revisions are highly welcome. [The same applies to the \*Acronyms\*.](#)

[Throughout the NMSOP-2 many links to external website have been given and their functioning been tested several times. However, we have realized that many institutions currently restructure rigorously \(or even close\) their previous websites. Thus, at the time of this writing, we found already some links not working that were still fully operational a few months ago. Therefore, neither the GFZ German Research Centre for Geosciences, nor the Editor or the authors can guarantee the correctness and functioning of any links given to external websites of institution, programs, firms of product. In case of link failures users are advised to “google“ for the respective “term”.](#)

In NMSOP-2 the names of authors and their addresses are given below the title of each Manual item. Several Chapters are collaborative work of all named authors, making it difficult to single-out individual contributions. The name of the main contributor or coordinator is then usually given first. Questions or comments should be addressed to him with a copy to the Editor. At times co-authors have contributed only to specific parts. When this case arises, their names are given in the list of contents behind the title of the respective sub-chapter/section. Questions or comments may then be addressed directly to these co-authors, again with a copy to the Editor and the main author of the Chapter for information. The same applies to annexed material.

The Manual contains many cross-references to figures, tables and equations in both Chapters and annexed items. The following nomenclature eases unambiguous cross-references:

- Annexed items are referred to by the acronym of their “class name” (e.g., DS; EX, IS, or PD) followed by the Chapter number to which they relate, and the sequence number, e.g., IS 2.1, EX 3.3, or PD 5.3.
- However, when referring to any sub-division of a Chapter we give only its respective number, e.g., see 4.2, or see 11.2.3.4.
- When referring to annexed items which relate to the Manual as a whole, we refer to the name of the folder (e.g., see Acronyms, Glossary, Prefaces, ...).
- Equations, figures and tables are numbered individually within each Chapter or annexed item; equation numbers are always given in brackets.
- Equation numbers in Chapters give first the Chapter number, followed by the sequence number of the equation within that Chapter, e.g., (5.7) or (3.43), whereas equations in annexed items are given by their sequence number only, e.g. (6).
- The same applies to figure and table numbers, with the exception that these numbers are not put in brackets, e.g. Fig. 5.3 or Tab. 3.1.
- References to figures, tables or equations in annexed items are made as follows: e.g., see Figure 4 in DS 11.2, or see Table 1 in EX 3.2, or see Equation (12) in IS 3.1.

NMSOP-2 offers access and download options via hyperlink to many computer programs, animations (educational movies), power point presentations and other types of files. The respective folder or file names are printed in the related texts in bold black. All these names are summarized in a listing of *Download programs and files* (see NMSOP-2 cover page). They can be downloaded and/or activated via hyperlink from this summary listing by right mouse click on the respective link names, which are printed in bold blue letters. Sub-routine or file names which are printed in this listing in bold black letters are only part of larger program packages. Related information, also about authors and the type of programs or files are given in this listing as well.

We use American English as consistently as possible, however some modifications may occur and hopefully will be tolerated. Experts from many nations have contributed both to the Manual drafts and the review process, thus different opinions about correct style, grammar and punctuation have been unavoidable. For example, there are pros and cons for writing either “Earth”, or “earth” depending on whether one refers to the whole planet or only parts of it. We opted for “Earth”, as in the old Willmore (1979) Manual. Accordingly, we speak of Earth models, Earth tides, etc. We avoided using the term ‘Earth’ when specifically referring to the Earth’s crust, lithosphere, mantle, or core. No consensus could be reached between American, Australian and English reviewers as to when to use the apostrophe (e.g., as in Earth’s Interior) and when not (as now common in Earth models or Earth systems). Therefore, we have tried to avoid its use. Despite all efforts, and taking into account that the majority of authors, including the Editor, do not have English as their mother tongue, typos, misnomers and occasionally clumsy phrasing may still be found. Some references to figures, equations, tables, publications or sub-sections may still be missing or incorrect; the Editor will be grateful for any suggestions and/or corrections.

Ten years ago, the IASPEI Working Group on Phase Names agreed on a list of standard phase names. It includes old, partially changed and new names. The list is reproduced in IS 2.1. It has been approved by IASPEI and was published by Storchak et al. in 2003, and, slightly modified, in 2011. As far as possible we have applied the new phase names, e.g., Pdif instead of Pdiff and PKPdf instead of PKIKP. Yet, some of the figures have been reproduced from other sources or have been plotted by programs for seismogram analysis that still use the old terminology. This explains some inconsistencies in the Manual with respect to phase names, but we strongly favour the consistent use of the standard phases names as given in IS 2.1.

With respect to magnitude symbols, different nomenclatures are used in NMSOP-2:

- a) the generic NMSOP (2002) nomenclature, which largely agrees with that in most pre-2010 seismological publication, with the exception of writing no subscripts and Ml instead of ML.
- b) the NMSOP (2002) specific nomenclature (see IS 3.2), because it describes unambiguously the type of seismic wave used for magnitude determination, the record component on which the amplitudes have been measured and the response type of the seismograph;
- c) the IASPEI (2011) nomenclature for standard magnitude and amplitude readings (see [http://www.iaspei.org/commissions/CSOI/Summary\\_WG-Recommendations\\_20110909.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG-Recommendations_20110909.pdf)), which we strongly advocate. The reasons are outlined in Chapter 3 and IS 3.3.

Furthermore, in all NMSOP editions we generally use the symbol D for epicentral distance instead of  $\Delta$ , which is more common in older literature. However, in magnitude formulas and

## Editorial Remarks

tables of calibration values we keep the  $\Delta$  as in the original formulas. Physical units are given consistently in accordance with the International System of weights and measures (SI units). Only occasionally reference is made to equivalent American units.

Finally, since several chapters and other manual items are still under major revision, some references in the now published manual contributions to other section, figure and/or table numbers are still followed by ???. This means that these numbers still relate to the respective items in the NMSOP-1 (2009) web edition or the related printed edition of 2002. The question marks will be deleted when the finally revised numbers of these items become available with the completed version of NMSOP-2.

Potsdam/Kleinmachnow, December 2011

  
Peter Bormann (NMSOP Editor)

## List of Reviewers

(as of January 2014)

All contributions in NMSOP-1 and 2 have been peer reviewed by international experts in the respective fields. Their names are given below in alphabetic order together with the numbers (in brackets) of the respective Chapters, Sections or auxiliary materials (DS, EX, IS, PD) reviewed by them. The Editor expresses his deep appreciation and thanks to all for spending their precious time in reviewing one or more contributions to this Manual, thus assuring the topicality and correctness of contents.

### 1.1 Introduction to the history of the manual editions

Most of what we know today about the internal structure and physical properties of the Earth, and thus about the internal forces which drive plate motions and produce major geological features, has been derived from seismological data. Seismology continues to be a fundamental tool for investigating the kinematics and dynamics of geological processes at all scales. With continued advances in seismological methods we hope to better understand and assess their current status as well as the diverse related potential benefits, hazards and risks for mankind.

Geological processes neither know nor care about human boundaries. Accordingly, both the resources and the hazards can be investigated and assessed effectively only when the causative phenomena are monitored not only on a local scale, but also on a regional and global scale. Moreover, geological phenomena typically must be recorded with great precision and reliability over long time-spans corresponding to geological time-scales. Such data, which are collected in different countries by different research groups, have to be compatible in subtle ways and need to be widely exchanged and jointly analyzed in order to have any global and lasting value. This necessitates global co-operation and agreement on standards for operational procedures and data formats. Therefore, it is not surprising that the international seismological community saw the need for developing a Manual of Seismological Observatory Practice (MSOP) already many decades ago.

This matter was taken up by the scientific establishments of many nations, finally resulting, in the early 1960s, in a resolution of the United Nations Economic and Social Council (ECOSOC). In response, the Committee for the Standardization of Seismographs and Seismograms of the International Association of Seismology and Physics of the Earth's Interior (IASPEI) specified in 1963 the general requirements of such a Manual as follows:

- act as a guide for governments in setting up or running seismological networks;
- contain all necessary information on instrumentation and procedure so as to enable stations to fulfil normal international and local functions; and
- not to contain any extensive account of the aims or methods of utilizing the seismic data, as these were in the province of existing textbooks.

The first edition of the Manual of Seismological Observatory Practice was published by the International Seismological Centre (ISC) in 1970 with the financial assistance of the United Nations Educational, Scientific and Cultural Organization (UNESCO). A sustained demand for copies and suggestions for new material prompted the Commission on Practice of IASPEI in 1975 to prepare a second edition. The authors worked to achieve balance between western and Soviet/Russian traditions of seismological practice. This resulted in the 1979 version of the Manual, edited by P. L. Willmore, in which the basic duties of seismological observatories were envisaged as follows:

- maintain equipment in continuous operation, with instruments calibrated and adjusted to conform with agreed-upon standards;
- produce records which conform with necessary standards for internal use and international exchange; and
- undertake preliminary readings needed to meet the immediate requirements of data reporting.

The "final" interpretation of seismic records was considered to be an optional activity for which the Manual should provide some background material only, with no attempt to fully cover it. On the other hand, the Manual did provide more detailed guidance for observatory personnel as required for the occasional, but at those times most important, collection and classification of macroseismic observations. In general, the international team of authors "...sought to extract the most general principles from a wide range of world practice, and to outline a course of action which will be consistent with those principles."

Even as the 1979 Edition of the Manual was published, it was obvious that there existed significant regional differences in practice and that the subject as a whole was rapidly

advancing. Since this implied the need for continuous development, it was decided to produce the book in loose-leaf form and to identify chapters with descriptive code names so as to allow for easy reassembling, updating and insertion of new chapters. This useful concept was not achieved, however, and no updating or addition of new chapters happened after the 1979 edition. Yet, the general aims of the old MSOP are still quite valid, although the scope of modern practice has broadened significantly during the last few decades, and although old analog recording stations and data analysis procedures have meanwhile been replaced by the corresponding digital ones practically everywhere. But for a deeper understanding and full appreciation of these recent tremendous developments in seismological practice it has been important that, along with the IASPEI Centennial International Handbook on Earthquake and Engineering Seismology (2002), the 1979 edition of the MSOP has been made available on CD-ROM, and is now accessible, together with the electronic NMSOP editions, on the IASPEI home page (<http://www.iaspei.org/projects/NMSOP.html>) as well.

Since the last edition of the MSOP, seismology has in fact undergone a technological revolution. This is driven by cheap computer power, by the development of a new generation of seismometers and digital recording systems with very broad bandwidth and high dynamic range, by digital analysis tools that run on complex algorithms based on most recent theoretical concepts of seismic source processes, wave generation and propagation as well as signal processing and, finally, by the advent and breathtaking global progress of the Internet as an effective vehicle for rapid, large-scale data exchange and communication. This, however, made more and more sections of the 1979 Manual obsolete or irrelevant, providing no more guidance in many areas of critical importance for modern seismology.

In a workshop meeting organized in late 1993 by the International Seismological Observing Period (ISOP) in Golden, Colorado, entitled "Measurement Protocols for Routine Analysis of Digital Data", it was acknowledged that existing documents and publications are clearly inadequate to guide routine practice in the 1990s at seismological observatories acquiring digital data. It was concluded that a new edition of MSOP is needed as well as tutorials showing examples of measuring important seismological parameters (Bergman and Sipkin, 1994). This recommendation prompted the IASPEI Commission on Practice (CoP) at its meeting in Wellington, New Zealand, 1994, to establish a MSOP Working Group (WG) entrusted with the elaboration of an IASPEI New Manual of Seismological Observatory Practice (NMSOP). Peter Bormann was asked to assemble and chair the working group and to elaborate a concept on the aims, scope and approach for a new Manual.

The first concept for the NMSOP was put forward at the XXIV General Assembly of the European Seismological Commission (ESC) in Athens, Greece, September 19-24, 1994 (Bormann, 1994) and in 1995 at the meeting of the IASPEI CoP on the occasion of the XXI General Assembly of the International Union of Geodesy and Geophysics (IUGG) in Boulder, Colorado. The concept was approved and both an IASPEI and an ESC Manual WG were formed. Most of the members met regularly at ESC and IASPEI Assemblies (ESC: 1996 in Reykjavík, 1998 in Tel Aviv and 2000 in Lisboa; IASPEI: 1997 in Thessaloniki, 1999 in Birmingham and 2001 in Hanoi) while others corresponded with the group and contributed to its work via the Internet. At these assemblies the Manual WG organized special workshop sessions, open to a broader public and well attended, with oral and poster presentations complemented by Internet demonstrations of the Manual web site under development. With a summary poster session at the IASPEI/IAGA meeting in Hanoi, 2001, the work of the IASPEI Manual WG was formally terminated and the WG chairman was entrusted with the final editorial work and the preparations for the publication of the Manual.

NMSOP was published in 2002 by the GeoForschungsZentrum (GFZ) Potsdam, Germany, with some financial support of IASPEI, as a hard cover loose-leaf collection of contributions in two volumes (Bormann, 2002; Fig. 1.1a). More than 2000 copies are meanwhile in use in more than 100 countries, several hundred copies alone bought and disseminated to seismological stations and member institutions by IASPEI, the Incorporated Research Institutions for Seismology (IRIS, USA) and the United Nations Comprehensive Test-Ban Treaty Organization (CTBTO). From feedback of users to the editor it is known that NMSOP has become not only a useful instruction material and guidance for the daily work of the personnel at seismological observatories and data analysis centers, but also for people working in field surveys taking along the NMSOP CD. Moreover, NMSOP Chapters and exercises are widely used by university lecturers as well as by trainers and participants in post-graduate international seismology courses.

In 2006 the Seismological Press Beijing published a Chinese translation of NMSOP as a two-volume book (Fig. 1.1b) and in 2010 the BMKG Indonesia, with support of the Japan International Co-operation Agency (JICA), issued a translation of the NMSOP Chapters 2-4 in Indonesian language (Fig. 1.1c), with more chapters still being in the process of translation.

Observatory practice relevant parts of NMSOP have been also translated into Russian by the Geophysical Survey of the Russian Academy of Sciences for use at its main seismological stations and networks and the first 4 Chapters have been translated also into Turkish by 2010.

**Fig. 1.1** First NMSOP editions in a) English, b) Chinese and c) Indonesian language.

Despite the undoubted success in the wide distribution and use of NMSOP there have been annoying hindrances in making this instructional and educational material available to those that mostly needed it, especially observatories and institutions in earthquake-prone developing countries. NMSOP had deliberately not been submitted for publication by one of the prestigious commercial publishers. To buy its 1250 pages on the international book market might then have cost a few hundred dollars and thus become unaffordable for many institutions, observatories and individuals in these countries. Therefore, the GFZ Potsdam decided to pay in advance for the pure printing cost and to assure free storing and handling of

the shipment to customers. However, it then turned out that the shipment cost to most countries for the two 5 kg volumes were twice as costly as their production, making NMSOP again not affordable for many.

It has been this sobering experience that let the Editor propose already in 2007 at the IUGG/IASPEI General Assembly in Perugia the elaboration of an amended second electronic edition, NMSOP-2, that was to be made freely available to any interested user. A detailed NMSOP-2 project plan, agreed with about two dozen potential old and new authors, was posted and adopted at the IASPEI General Assembly early 2009 in Cape Town, South Africa, and a special IASPEI symposium on NMSOP-2 was planned to be held in conjunction with the IUGG General Assembly in Melbourne, 2011. As a first step into the direction of an electronic NMSOP the GFZ library put a slightly revised version of the first NMSOP edition, NMSOP-1 (Bormann, 2009), with doi-numbers for each reviewed contribution, on the Internet. It is accessible via <http://www.iaspei.org/projects/NMSOP.html>.

NMSOP-2 developed gradually. The first rigorously revised and largely amended Chapters, Information Sheets and Exercises of NMSOP-1 became available already in fall 2011, complemented by several new Chapters and rich auxiliary material by early 2012. On the other hand, quite a number of scheduled contributions could not be finalized in the planned time, due to both the serious chronic disease of the Editor and unforeseen priority obligations beyond the control of several committed authors. This led to the decision to open already in spring 2012 the NMSOP-2 website at <http://nmsop.gfz-potsdam.de> with the already available material. Even some contributions still under review, but earmarked differently, and amended by NMSOP-1 papers that remained either unchanged or were still under revision, were published. Thus, NMSOP-2 was “born” as – and will remain in future - a *dynamic publication*. It will develop and grow according to changing needs, new priorities, and available potentials in close collaboration between the IASPEI Commission on Seismic Observation and Interpretation (CoSOI) and the GFZ German Research Centre for Geosciences in Potsdam. The GFZ central library will assure the long-term competent maintenance of the NMSOP website. But at the same time the NMSOP is supposed to be also a mirror of the development of basic concepts, procedures and assumptions on which seismological observatory practice rests. Otherwise neither the reasons nor the appropriate ways for assuring long-term data continuity, stability and compatibility in Earth science will be understandable to the younger generation growing up in the computer age with its breathtakingly rapid changing possibilities and appealing new options.

By the end of 2013 more than 2000 Manual pages will be available for reading and downloading. They include, besides the 16 basic topical overview Chapters, plenty of complementary material such as specialized topical Information Sheets, Data Sheets, Tutorials, Exercises and Program Descriptions, Acronym explanations as well as the largest ever so far published Glossary of terms in seismology and related fields (see website cover page). Future NMSOP updates and complements will now be the main responsibility of the individual contributing authors and of IASPEI/CoSOI, in order to adapt to changing needs, newly developed procedures and gained insights. There is no more need to wait for an overall revision and new edition of the Manual before updates or complements can be made. This makes it easy to assure that with the Manual there will be in the field of seismological practice, which is usually not or only very marginally taught at universities, always a competent up-to-date educational and instructional material available. And many of its modules, animations and programs have proven to be even attractive at high-school level, suitable for promoting interdisciplinary problem understanding in general.

## 1.2 Scope of the NMSOP

### 1.2.1 Observatory seismology: Historically and regionally changing concepts, conditions and approaches

Emil Wiechert (1861-1928), professor of geophysics in Göttingen, Germany, and designer of the famous early mechanical seismographs named after him, had the following motto carved over the entrance to the seismometer house in Göttingen: “Ferne Kunde bringt Dir der schwankende Boden - deute die Zeichen.” (“The trembling rock bears tidings from afar – read the signs!”; see link to the dedication of this Manual to Emil Wiechert and Boris Galitzin). Wiechert also considered it as the supreme goal of seismology to “understand each wiggle” in a seismic record. Indeed, only then would we understand or at least have developed a reasonable model to explain the complicated system and “information chain” of seismology with its many interrelated sub-systems such as the seismic source, wave propagation through the Earth, the masking and distortion of “useful signals” by noise, as well as the influence of the seismic sensors, recorders and processing techniques on the seismogram (see Fig. 1.2).

**Fig. 1.2** Scheme illustrating seismology as the analysis of a complex information system linked to a diversity of specialized and interdisciplinary tasks of research and applications.

During the early years of seismology analog seismic records have been precious unique documents for each station. Lending and shipping them to interested researches at other stations, even abroad, was a risky undertaking. Many valuable records got lost this way. Therefore, it has been a must to extract from each record as many as possible seismic phases

and other parameter data and publish them in bulletins which could be printed and distributed instead of shipping original seismograms.

Yet, despite the tremendous progress made since Wiechert's time in understanding the most prominent features in seismic records, long-period ones in particular, we are still well short of reaching the goal he set. In fact, most operators and analysts at seismological observatories, even those who work with the most modern equipment, have not advanced much beyond the early 20<sup>th</sup> century with respect to their capability to understand and assign a proper "name" to each wiggle in a seismic record and to report their findings to international data centers. Even worse, some of the data centers are not even prepared to accept, publish and archive more detailed data reported to them if they consider them as not relevant for their duties. This has even discouraged many station and national data center operators to measure and/or report more phase data than those explicitly requested, e.g., by the NEIC of the USGS. Even pronounced seismic phases such as S shear-waves arrivals, which used to be almost as often measured and reported as P-wave arrivals before the 1960s, have often no longer been measured by many stations after the installation of the US World-Wide Standard Seismograph Network (WWSSN) in the 1960s and after the National Earthquake Information Center (NEIC) of the US Geological Survey and the International Seismological Center (ISC) in the United Kingdom (UK) resumed their operations (see Hwang and Clayton, 1991, and Figs. 1.3 -1.5). This happened irrespective of the unique importance of S-wave travel-time and amplitude readings for improving the shear-wave velocity and attenuation structure of the Earth and thus our understanding of the properties of the Earth matter.

**Fig. 1.3** Annual number of arrival times of P-waves (red) and S-waves (blue) used to produce the ISC-GEM (Global Earthquake Model project) catalogue (see Storchak et al., 2013; Bondár et al., 2013; Di Giacomo et al., 2013a,b). Different data sources were used: Before 1918 the body-wave arrival data was collected from Gutenberg's notepads (1904-1912), the International Seismological Association (ISA; 1904-1907), the British Association of the Advancement of Science (BAAS; 1913-1918) and seismological station bulletins (since 1904); between 1918 and 1963 from the International Seismological Summary (ISS) and seismological station bulletins; from 1964 until the end of 2009 from the ISC Bulletin. (Figure by courtesy of Domenico Di Giacomo, ISC, 2013).

According to Fig. 1.3 the pre-1960 annual frequency of S-wave arrival times measured and documented in bulletins varied between about 55 to 100% of the P-wave readings. Since the 1960s this percentage has never been more than 40% in the ISC bulletins, dropped in recent years down to about 10%, and is even less in NEIC bulletins (PDE and EDR) (compare in Fig. 1.4 the CLL data in NEIC and ISC bulletins). There are two main reasons for this growing discrepancy. Firstly, for decades event location at both the NEIC and the ISC has been based solely on short-period P-wave first arrivals which also yielded the amplitude data for the short-period magnitude  $m_b$ , the exclusive classical body-wave magnitude calculated at the NEIC. So there seemed to be no explicit need for reporting and using of any other later body-wave onsets. Secondly, high-gain short-period narrowband seismographs introduced with the WWSSN into global standard monitoring practice allowed to increase the number of detected events by one order and even more. But for weaker events only P-waves have still a sufficient signal-to-noise ratio (SNR) in short-period filtered high-gain records, not, however, S waves located in the much noisier broadband or long-period records.

Fig. 1.4a compares the relative frequency of secondary phase onset readings to respective P and PKP readings in bulletins of the seismic station MOX in Germany. It dropped strongly from the first bulletins between 1965-67 (published by the author) to the last decade of printed bulletins (1974-84). But even from the latter data not all S, SS and PKP2 readings were included in the ISC bulletin. Even more striking is the difference between the number of secondary phase data analysed between 1990 and 1995 at the seismological observatory CLL, Germany, and the number of phase data accepted by the ISC and (much less) by the NEIC in their bulletins (Fig. 1.4b).

**Fig. 1.4a** Relative frequency of the measurement of identified secondary wave onsets as compared to P and PKP first arrivals by the author in early bulletins of station Moxa, Germany (squares), in later bulletins of station Moxa (triangles) and by the global network of seismic stations reporting to the ISC (diamonds).

**Fig. 1.4b** Travel-time plots over epicentral distance of all seismic onsets analyzed at the observatory Collm (CLL), Germany, during the years 1990-95 (right-hand panel) and of the onsets reproduced for the same station during the same time span in the bulletins (EDR's) of the NEIC=NEIS (left-hand panel) and the ISC (central panel), respectively (Figure by courtesy of S. Wendt).

According to Bergman (1991), the first S-wave arrivals were reported on average to the ISC about twenty times less frequently than P, and other secondary phases were reported hundreds to thousands of times less often. These differences reflect operations practice at least as much as the usually reduced detectability of secondary phases. Because the NEIC did normally not use S phases in its routine processing, US station operators tended to interpret such readings as "wasted time". As a consequence, US stations reported between 1974 and 1984 also very seldom S-wave data to the ISC. Conversely, a heavy proportion of all S readings came from European and Asian stations, especially those in former Soviet Bloc countries, China and Japan, where standards of practice included an emphasis on complete reading of seismograms (Fig. 1.5).

**Fig. 1.5** Relative frequency of reported S/P arrivals to the ISC by stations of the global seismic network during the decade 1974 to 1984. Note the embarrassing disregard of measuring S-wave arrivals, especially in the western Americas, Africa and Australia (Figure published by Doornbos et al., 1991).

Hwang and Clayton (1991) published a revealing analysis of the phase reports to the International Seismological Centre (ISC) by all the affiliated seismological stations of the global seismic network. Most of them, even those equipped with both short- and long-period or broadband seismographs, reported only the first P-wave onset even though later energy arrivals in teleseismic records of strong events are clearly discernible, even in fully automatic simple threshold detection procedures (see Chapter 2, Fig. 2.58), although much less frequently in short-period filtered records (Fig. 2.57). Even secondary phases with much larger amplitudes than P (e.g., Figs. 1.6 and 1.10, Fig. 2.25 in Chapter 2 and Figure 10c in DS 11.2) were usually not analyzed. And this situation has not generally changed to the better since then, rather often even worsened.

The scarcity of seismic body-wave phase readings, especially of depth phases, has strongly limited the accuracy of global seismic event locations (see Figure 7 in IS 11.1 and Engdahl et al., 1998). The same applies to the derived seismic velocity models, because the very limited number of frequently measured seismic body-wave phases is not able to sample the various lateral and depth ranges of the Earth homogeneously. This led IASPEI to launch the initiative for an International Seismological Observing Period (ISOP; see Doornbos et al., 1991). ISOP was scheduled to take place during the 1990s and aimed at training station operators in better recognizing, measuring (onset times, amplitudes and periods) and reporting relevant secondary seismic phase arrivals and providing suitable software tools for these tasks. The outcome of this initiative was supposed to assure a greatly improved and much more homogeneous future seismological database for the derivation of more detailed and better constrained structural, physical and compositional Earth models. Regrettably, after intensive preparations the project had to be cancelled even before proper take-off, because of drastic cuts in personnel at the planned ISOP co-ordination and analysis center at the NEIC. But this essential task still remains to be tackled in future. NMSOP offers a broad array of arguments, record data, seismological methods and suitable software tools to work in this direction.

**Fig. 1.6** Long-period filtered vertical-component broadband records of station CLL, Germany, of shallow earthquakes in the distance range  $18^\circ$  to  $157^\circ$ . Note the strong later longitudinal (PP) and transverse energy arrivals (S, SS) that are recognizable in the whole distance range, and the dispersed surface wave trains with large amplitudes. The record duration increases with distance (courtesy of S. Wendt, 2002).

There are several reasons for the lack of progress in the deeper understanding of seismogram analysis by station operators. Early seismic stations were mostly run or supervised by broadly educated scientists who pioneered both the technical and scientific development of these observatories. They took an immediate interest in the analysis of the data themselves and had the necessary background knowledge to do it. After World War II the installation of new seismic stations boomed and rapid technological advance required an increasing specialization. Station operators became more and more technically oriented, focusing on equipment maintenance and raw data production with a minimum of effort and interest in routine data analysis. Thus, they have tended to become separated from the more comprehensive scientific and application-oriented use of their data products in society. Also the seismological research community itself has become increasingly specialized, e.g., in conjunction with the monitoring and identification of underground nuclear tests. This trend has often caused changes in priorities and narrowed the view with respect to the kind of data and routine analysis required to better serve current scientific as well as public interest in earthquake seismology, improved hazard assessment and risk mitigation.

As a consequence, "classical" seismological observatories, as, e.g., Moxa (MOX) and Collm (CLL) in former East Germany (see Figs. 1.4a and b), belong now to an "endangered

species". They depended on a social and political system that was prepared to devote relatively large numbers of personnel and other resources to station operation and analysis, with the goal of extracting the maximum amount of information out of a limited number of recordings. One can think of this as the "observatory-centered" model for observational seismology. Beginning in the 1960s, seismology in the West favored deployment of global networks (e.g., the WWSSN - World-wide Standard Seismograph Network) with relatively less attention given to individual stations or records, making up in quantity what they gave away in quality. This "network model" of observational seismology now dominates global seismology. But a reasonable balance between quantity and quality has to be preserved. This Manual is explicitly intended to support the side of quality and completeness in the acquisition, processing, and analysis of seismic data. Currently some excesses in a pure network-centered model of observatory seismology are already questioned. In its report 2013 to CoSOI the IASPEI Working Group on Magnitude Measurements states:

*" The number of digital stations world-wide has increased dramatically, so that it is not unusual for the NEIC to have several thousand amplitude/period observations for a single, moderately strong, earthquake, .... At the NEIC, this situation has led to consideration of computing magnitudes only for a preferred subset of the overall station set, with preferred stations being selected on the basis of such criteria as geographic location, station sensitivity and reliability, or extent to which current observations would continue a long-running data set."*

Interestingly, this concept had already been proposed some 30 years ago at the time of analog seismology. It aimed at the creation of a homogeneous magnitude system (HMS) for Eurasia, based on a sub-set of first-rate stations, improved calibration functions, taking into account carefully determined station residuals for reducing drastically the data scatter in estimating event magnitudes, etc. But the proposal, although widely published (Christoskov et al, 1978; 1983; 1985; 1991), was not followed up further by the IASPEI magnitude WG and even discredited by the believers in the global network mass-data approach. Similarly, many other procedures discussed, examples presented and recommendations given in the NMSOP may appear for today's reader to be old-fashioned and off the current mainstream. This, however, should not prevent realizing their rationale and considering seriously how they might be taken into account in the modification/amendment of current procedures.

The accelerating advancement of computer capabilities during the last few decades is a strong incentive to automate more and more of the traditional tasks that need to be performed at seismological observatories. Most decision makers in seismology consider nowadays detailed seismogram parameter readings and event location nothing but time consuming and boring routine tasks, not worth paying qualified manpower for it with the exception of a clever programmer to automate these tasks. Such an assessment is apparently supported also by the facts that we can nowadays

- exchange world-wide full seismic waveform data/seismograms electronically, so that high-quality data for parameter extraction or specific research are now available (almost) everywhere (see IS 8.3);
- make use of algorithms and software for reliable and robust phase picking;
- synthesize the most important basic features in medium- to long-period seismic records;

- derive information on the source process, structure and properties of the medium from fitting synthetic waveforms to measured ones.

However, despite significant progress made in this direction, automated phase identification and parameter determination is still inferior to the results achievable by a well-trained analyst (see Chapter 3, section 3.2.3.2; Chapters 11 and 16). And for short-period records synthetics of both travel-times and waveforms look still rather different from records in real 3D media (see, e.g., Chapter 2, Fig. 2.85 and Figures 3 und 4 in IS 11.4.). Although it is likely that in future good documentations of progress made in detailed automatic seismogram interpretation can be added to the NMSOP, this second edition still heavily focuses on providing guidance, based on rich empirical experience, to: (i) the developers of software for interactive and automatic routines, (ii) to station operators and seismologists with less experience and (iii) to countries which lack specialists in the fields that should be covered by well-educated observatory personnel and application-oriented seismologists. But good knowledge of the complexity and diversity of actual body-wave waveforms is not only important for manual seismogram interpretation, but also for basic research and the development of appropriate methodologies and algorithms in general.

In any case, even in developing nations, observatory personnel has nowadays computers and software for seismogram analysis together with Internet connection for downloading the NMSOP and free shareware. During the classical analog days station analysts reading parametric data on records with fixed and limited time resolution and dynamic range, and performing their calculations with the aid of map projections, nomograms, travel-time curves, tables and logarithmic rulers, could not even dream of such comfortable tools.

Digital data, using such interactive analysis and processing tools in connection with real-time data links (see IS 8.3) and (virtual) network/array data processing (Chapters 8 and 9), now open the door for:

- Filtering standard and non-standard instrument responses;
- Phase identification using theoretical travel-times;
- Three-component processing and thus phase identification and event location based on polarization criteria;
- Hilbert transform to correct for phase distortions at caustics;
- Routine determination of spectral source parameters;
- Source parameter determination and phase identification by fitting synthetic seismograms to real seismic records;
- Frequency-wavenumber filtering and thus the application of array-processing for improved event detection, event location and phase identification;
- Automatic report generation.

Despite all these potential benefits, it is a fact that digital stations are increasingly less frequently read manually in a comprehensive way; if they are, then it happens usually only for strong events at first-order main analysis centers or at lucky stations that still have one or more well-trained analysts. Therefore, in the context of planning for ISOP, E.R. Engdahl and E. Bergmann asked already in a 1994 IASPEI talk the following question:

*“Why does detailed routine seismogram analysis discontinue when modern digital data acquisition, processing and analysis tools become available although they significantly ease and improve to achieve ISOP goals?”*

For an ISOP Pilot experiment between September 1993 and April 1994, 33 stations had been selected worldwide. The task was to identify and report secondary phase arrivals after P or PKP from records of some strong earthquakes with clear records of such secondary phases. 30% of the participating stations reported in the average less than one later onset. Only five stations, all from Eastern Europe, reported on the average four or more later onsets!

What are the reasons for such a disturbing development?

- Narrow-band high-frequency data, also from seismic arrays, lowered the detection threshold by at least 1 magnitude unit, i.e., the amount of data to be analyzed at WDCs increased by more than a factor of about 10.
- The tremendous increase of the number of stations in many seismically active countries decreased detection thresholds and increased the number of records even further.
- Nobody wants (or gets the money) to pay for more qualified manpower needed to carry out high-level routine analysis of these much improved modern data for general use. To the contrary, funds for so-called “routine tasks” are decreasing everywhere.
- Such a budget policy and lacking commitment of governments to assure sustained funding for high-quality long-term monitoring programs kill scientifically meaningful and necessary tasks.

When reading through the Manual, especially through Chapter 3 on seismic source parameters and through Chapter 11 on seismogram interpretation with their associated Data Sheets and Exercises, it becomes soon very clear that there is no simple stupid routine in measuring the relevant parameters. Even worse, the deviations from some simplified general rules are the most important ones to identify, measure and document. Rapid automatic default analysis programs can only work efficient on the basis of simplified general rules. Their development requires software specialists who usually possess, however, only a very basic understanding of the measurement parameters. On the other hand, the analysts trained over many years of analyzing tens of thousands of such parameters in all their diversity for earthquakes in very different distance, depth and magnitude ranges, do not usually have the top programming expertise needed for the development of highly efficient complex automatic data processing and analysis systems. Finally, an efficient communication and co-operation between these two types of experts as well as a comprehensive systematization and codification of complex empirical expertise, is also not a trivial task. Therefore, preserving and promoting rich empirical expertise, gained by daily tedious work with real data, preferably associated with a broad-enough seismological problem and with a good theoretical background understanding, is the indispensable precondition for any real progress in valuable automation efforts. In any event, the latter should be restricted to simplified rapid mass data handling and processing jobs and to those where rapidity counts most, and not to achieve data completeness, accuracy and novelty/peculiarity of the extracted information. The programmer and the empirically working seismologist have to be equally valued partners and the latter should not be discredited by considering him to be occupied with futile and boring routine work. NMSOP therefore focuses on the diversity and breathtaking complexity of the work with real seismological waveform data, which is usually only a minor part in most seismology text books.

In designing the Manual for a global audience, we have tried to take into account the widely varying circumstances of observatory operators worldwide. Whereas in developing countries proper education and full use of trained manpower for self-reliant development has (or should have) priority, highly advanced countries often push for the opposite, namely the advancement of automatic data acquisition and analysis. The main reasons for the latter tendency, besides the desire to limit personnel costs in high-wage countries, are:

- special requirements to assure a most rapid and objective data processing and reporting by the primary (mostly array) stations of the International Monitoring System (IMS) in the framework of the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) (see Chapter 15);
- coping with the huge data rates at dense digital seismic networks and arrays in areas of high seismicity;
- extracting within seconds or minutes only the most important first information from local, regional and/or global virtual network data on strong earthquakes with great risk potential (tsunami and earthquake early warning systems), which is required to assist risk mitigation, disaster management and relief operations.

Seismologists in highly industrialized countries can usually address their special concerns and requirements to national forums. Specialists in program development and automation algorithms in these countries, however, often lack the required background knowledge in seismology and/or the practical experience of operational applications in routine practice. A similar argument applies to young scientists, beginning their careers in seismological research, who often remain ignorant of the long history of operational seismology that produced the data now available for their research. A typical graduate program in seismology gives scant attention to the historical development of methods and measurement standards. This may lead either to neglect valuable older data and results, or to their incorrect interpretation and usage. In this sense, the NMSOP also aims at passing on the knowledge, experience and skills of previous generations of seismologists by addressing the educational needs of current highly specialized advanced user communities with a view to broaden both their historical and topical perspective, as well as their ability to contribute more efficiently to interdisciplinary basic research and methodological development.

## **1.2.2 Creation of awareness**

The subject of standards of practice at seismological observatories normally stays well below the active consciousness of most seismologists, yet it sometimes plays a central role in important research and policy debates. Also the awareness of the tremendous impact of recent technological advances, in both sensor developments and data communication, on the observatory and monitoring practice is not yet generally well developed. Even less developed is the understanding of the need for a much more detailed reading and reporting of secondary phases, not only of their onset times for improved event location but also of their amplitudes and periods for the determination of magnitudes and the derivation of improved attenuation models. However, both development and proper use of appropriate modern analysis tools require a profound understanding of seismic waveform data, their properties and variability. Moreover, accurate amplitude readings and reliable waveform-fitting inversion procedures require careful instrument calibration, i.e., knowledge of the transfer function and gain of the seismographs. However, there is no common standard practice yet of instrument calibration

and control. And finally, both the earthquake rupture process and the wave propagation are highly kinematic-dynamic phenomena, which are too often only explained with simplified static images and the 3D event patterns by their 2D projections. We believe that for their illustration animations are often much more suitable to create awareness of the complexity of these phenomena, easier to comprehend and much more appealing. Therefore, animations are a very valuable complementary educational tool to formal lectures, tutorials and exercises, suitable not only for academic and professional audience but also for public lectures and demonstrations at high schools. Therefore, the number and topics of animations has been significantly increased in NMSOP-2 (see IS 1.1 and IS 11.3). Yet, this is just a beginning. More such examples from other authors and on other subjects related to seismology and seismic effects are very much welcome. Authors are kindly invited to link their contributions to NMSOP-2. We will come back on some of these issues in the sections below.

### 1.2.2.1 The magnitude issue

Earthquake magnitude is one of the most widely used parameters in seismological practice, and one that is particularly subject to misunderstanding, even among seismologists. A striking example on how changing operational procedures have contaminated a valuable data set has been published by Hutton and Jones (1993). After re-examining the earthquake catalogue for southern California between 1932 and 1990 they concluded:

- ML magnitudes (in the following termed Ml with l for “local”) had not been consistently determined over that period;
- amplitudes of ground velocities recorded on Wood-Anderson instruments and thus Ml were systematically overestimated prior to 1944 compared to present reading procedures;
- in addition, changes from human to computerized estimation of Ml led to slightly lower magnitude estimates after 1975;
- these changes contributed to an *apparently higher rate of seismicity* in the 1930’s and 1940’s and a later decrease in seismicity rate which has been interpreted as being related to the subsequent 1952 Kern County ( $M_w = 7.5$ ) earthquake;
- variations in the rate of seismic activity have often been related to precursory activity prior to major earthquakes and therefore been considered suitable for earthquake prediction;
- the re-determination of Ml in the catalogue for southern California, however, *does not confirm any changes in seismicity* rate above the level of 90% significance for the time interval considered.

Similar experiences with other local and global catalogues led Habermann (1995) to state:

*“... the heterogeneity of these catalogues makes characterizing the long-term behavior of seismic regions extremely difficult and interpreting time-dependent changes in those regions hazardous at best. ... Several proposed precursory seismicity behaviors (activation and quiescence) can be caused by simple errors in the catalogues used to identify them. ... Such mistakes have the potential to undermine the relationship between the seismological community and the public we serve. They are, therefore, a serious threat to the well-being of our community.”*

Two striking examples of the consequences of disregarding procedural and nomenclature differences of teleseismic magnitude data, or even deliberately misusing them in the interest of political priorities, are given below:

Classical seismology was based on the recordings of medium-period instruments of relatively wide bandwidth such as Wiechert, Galitzin, Mainka, and Press-Ewing seismographs. Gutenberg's (1945 b and c; 1956) and Gutenberg and Richter's (1956 a and b) work on earthquake body-wave magnitude scales for teleseismic event scaling and energy determination was mainly based on records of such seismographs. Then, with the introduction of the WWSSN short-period instruments, body-wave magnitudes were determined routinely in the United States only from amplitude-measurements of these short-period narrowband records, which have better detection performance for weaker events than medium- and long-period seismographs and yield a better discrimination between earthquakes and underground nuclear explosions on the basis of the mb-Ms criterion (see 11.2.5.2 and Chapter 15). However, American seismologists calibrated their amplitude measurements with the Gutenberg-Richter Q-functions for medium-period body waves. This resulted in a systematic underestimation of the P-wave magnitudes (termed mb). In contrast, at Soviet "basic" stations, the standard instrument was the medium-period broadband Kirnos seismometer (displacement proportional between about 0.1 s to 10 s, later even 20 s. Accordingly, Russian medium-period body-wave magnitudes mB are more properly scaled to Gutenberg-Richters mB-Ms and logEs-Ms relations. Thus it happened that the corresponding global magnitude-frequency relationship logN-mB yielded a smaller number of annual  $m = 4$  events than the U.S. short-period mb data (Riznichenko, 1960). Accordingly, in the late 1950s at the Geneva talks to negotiate a nuclear test ban treaty, the US delegation assumed a much larger number of not reliably discriminated seismic events per year, since only teleseismic records were available to them. This prompted them to demand some 200 to 600 unmanned stations on Soviet territory at local and regional distances as well as on-site inspections in case of uncertain events (Gilpin, 1962). Thus, a biased magnitude-frequency assessment based on equalizing mb and mB played a significant role in the failure of these early negotiations aimed at achieving a Comprehensive Nuclear-Test-Ban Treaty (CTBT). The underground testing continued for several more decades.

In 1996 the CTBT was finally agreed upon, and signed by 71 States as of 2002. The United Nations CTBT Organization in Vienna runs an International Data Centre (IDC) that also determines body-wave magnitudes from records of the International Monitoring System (IMS). However, in the interest of the best possible discrimination between natural earthquakes and underground explosions by means of the body-wave/surface-wave magnitude ratio mb/Ms, they measure P-wave amplitudes after filtering the broadband records with a displacement frequency-response peaked around 4.5 Hz instead of around 1 Hz or 0.1 Hz. However, they calibrate their amplitude readings with a calibration function developed for 1 Hz data. Finally, they measure the maximum amplitudes for mb determination not, as recommended by IASPEI in 1977, within the whole P-wave train, up to 60 s after the first onset, but within the first 5.5 seconds after the P-wave onset. These differences in practice result in systematically smaller mb(IDC) values as compared to mb(NEIC). Although this difference is negligible for explosions, it is significant for earthquakes. The discrepancy grows with magnitude and may reach 0.5 to 1.5 magnitude units. Nonetheless, the IDC magnitudes are given the same name mb, although they sample different properties of the P-wave signal. Users who are not aware of the underlying causes and tricky procedural problems behind magnitude determination, may not realize this incompatibility of data and

come to completely different conclusions when using, e.g., the mb data of different data centers for seismic hazard assessment.

Such inconsistencies in the procedures to determine and name magnitude prompted IASPEI to set up again in 2002 a Working Group on magnitude measurements. It aimed at elaborating measurement standards for widely used magnitudes. The results are summarized in the Working Group recommendation (IASPEI, 2005 and 2013) and discussed in great detail in NMSOP-2, also with respect to the relationship between classical magnitudes and the newly proposed standards (see Chapter 3, sections 3.2.4, 3.2.5; IS 3.3 and 3.4).

But there are other important magnitudes, such as the moment magnitude  $M_w$  which is even considered to be an exclusively recommended *de facto* standard, that are determined with not yet standardized procedures using different wave types and period ranges. Accordingly, their magnitude values for identical events may differ by several tenths of magnitude units, such as for different versions of USGS moment magnitudes (see, e.g., Chapter 10, Tab. 10.5), or between authoritative Global Centroid Moment Tensor (GCMT) solutions and various rapid  $M_w$  proxy estimates that are available already within the first few minutes after origin times. Even magnitude estimates from the very first few seconds of a seismic record in earthquake early warning (EEW) schemes may underestimate the magnitude of strong to great ( $M > 8$ ) earthquakes by more than one magnitude unit. All these different types and procedures of magnitude estimation, the reasons for discrepancies and magnitude saturation, as well as the development of non-saturating near real-time magnitude procedures in the earthquake and tsunami early warning context, are discussed in detail in Chapter 3 and on specific issues also in IS 3.3 and IS 3.9 of this Manual.

### 1.2.2.2 Consequences of recent technical developments

When assembling the NMSOP we took into account that:

- modern seismic sensors (Chapter 5 and DS 5.1), in conjunction with advanced digital data acquisition (Chapter 6), transmission (Fig. 1.7, IS 8.2 and 8.6) and processing, allow event and magnitude determination (Fig. 1.8), as well as the analysis of seismic waves (Chapters 9 and 11), in a very broad frequency band with extremely high resolution within a much larger dynamic range (Fig. 1.9 and Fig. 4.7 in Chapter 4) and within a much shorter time than it was possible in the days of analog seismology;
- modern computer hardware and versatile interactive analysis software tremendously ease the task of comprehensive and accurate seismogram analysis (e.g., IS 11.6). This allows one to routinely determine also parameters which were far beyond the scope of seismogram analysis a few decades ago;
- precise time-keeping and reading is nowadays much less of a problem than it was in the pre-GPS (Global Positioning System) and pre-computer era;
- the rapid global spread of high-speed communication links largely eliminates any technical barrier to widespread data exchange of full waveform data in near-real time.

Fig. 1.7 Principal scheme of a modern ocean-spanning data acquisition and transmission system for seismological and complementary geodetic and oceanographic data as required for a tsunami early warning system (item names in German, courtesy of GFZ, Potsdam).

Fig. 1.8 Screen plot of the results of earthquake location and magnitude determination within the first few minutes after origin time using stations of the German-Indonesian Tsunami Early Warning System (GITEWS; <http://www.gitews.org>) and the GFZ developed SeisComp3 Software (<http://www.seiscomp3.org/>).

**Fig. 1.9** Frequency range, bandwidth and dynamic range covered by modern seismological records and related objects of research. The wavelengths of seismic waves vary, depending on their period and propagation velocity, between several meters (m) and more than 10,000 kilometers (km) and the spatial resolution of the investigated objects accordingly. The ground motion displacement amplitudes considered here range from nanometer (nm) to decimeter (dm). Continuous GPS may even measure displacements between cm and several m. Respective velocity amplitudes range between about 1 nm/s to several dm/s, however, strong-motion seismometers may even record accelerations up to about  $20 \text{ m/s}^2$  ( $\approx 2 \text{ g}$ ). When investigating with seismic methods even small-scale upper-crustal and near-surface structures or when recording induced seismic events in industrial seismology applications in conjunction with mining activities, liquid waste disposal, hydro-carbon extraction, tunnel drilling, or non-destructive material testing, even much higher frequencies than 50 Hz, up to MHz (ultrasound), may need to be recorded. This is, however, beyond the scope of the NMSOP.

At the same time, these new possibilities carry new risks:

- analysts who only use ready-made computer programs for solving a diversity of tasks, by feeding in the data and pressing the button, tend to lose a deeper understanding of the underlying model assumptions, inherent limitations and possible sources of error, and the quality of the results is sometimes judged by the attractiveness of the graphic user interface;
- Easily calculated and displayed standard deviations for all conceivable solutions often seem to indicate a reliability of the results, which is far from the truth. Therefore, an understanding of the difference between internal, computational and also model-dependent *precision* on the one hand, and *accuracy* of the solutions with

reference to reality on the other hand, has to be encouraged (see Glossary for the definition of terms);

- specialists are increasingly required to operate and properly maintain modern seismic equipment and software. They usually lack a broader geo-scientific background and thus an active interest in the use of the data themselves. This may result in a declining concern for long-term data continuity and reliability, which is the backbone for any geo-scientific observatory practice.

In consideration of these factors, the authors took as prime aims of the new Manual:

- to create an interdisciplinary problem understanding;
- to present a multitude of seismic waveforms depending on source type and size, epicentral distance, hypocentral depth, seismic component decomposition and axis rotation, transfer function of the seismic recordings, and with respect to the applied filters;
- to provide guidance for the selection of the most suitable station sites and the installation and shielding of modern seismic stations, vaults and sensors;
- to provide guidance for using modern tools and procedures for seismological data acquisition, processing and analysis;
- to motivate observatory personnel to overcome boring routines by developing curiosity and an active interest in the use of the data they produce both in science and society;
- to provide material for teaching, from high school to Bachelor and Master levels.

### **1.2.2.3 The need for secondary phase readings**

The currently still dominant practice of analyzing and reporting mainly first-arriving seismic phases results in conjunction with the inhomogeneous distribution of seismic sources and receivers over the globe results in a very incomplete and inhomogeneous sampling of the structural features and properties of the Earth's interior. The consequences are not only ill-constrained Earth models of low resolution, but also earthquake locations of insufficient accuracy (with mislocations up to several tens of km). This is reflected in the difficulty in understanding the seismotectonic origin of earthquakes and in the identification of the most likely places of their future occurrence. This prompted seismologists in the late 1980s (e.g., Doornbos et al., 1991) to conceive an International Seismological Observing Period (ISOP) aimed at:

- maximizing the reports of secondary phases from routine record readings aimed at improving source locations and sampling of the Earth (e.g., Fig. 1.10);
- taking best advantage, in the routine analysis, of the increasing availability of digital broadband records and easy-to-use data preprocessing and analysis software;
- improving the training of station operators and analysts;
- improving the communication, co-ordination and co-operation between the stations of the global and regional seismic networks.

**Fig. 1.10** Detailed interpretation of long-period (LP) and short-period (SP) filtered broadband records of the stations of the German Regional Seismic Network (GRSN). Note the clearly recognizable depth phases pP, pPP and sS, which are extremely important for a more accurate depth determination of the event (see Figure 11 in IS 11.1), as well as the rare but well developed multiple core phases PKPPKP, SKPPKP and SKPPKPPKP which sample very different parts of the deep Earth's interior than the direct mantle phases (courtesy of S. Wendt, 2002).

Ultimately, the ISOP plan for an international observational experiment focused on expanded reporting of secondary body wave phases collapsed in the face of entropy and inertia, but the issues raised in the ISOP project have remained important to many seismologists. The need for the NMSOP grew out of discussions within the ISOP project and has been developed in the spirit of ISOP. It is largely based on training material and practical exercises used in international training courses for station operators and analysts (see Bormann, 2000). Accordingly, Chapter 11 on Data Analysis and Seismogram Interpretation is, together with its extended annexes of seismogram examples (DS 11.1-11.4), information sheets and exercises on event location and phase identification together with related software the most extensive part of the NMSOP.

#### **1.2.2.4 New seismic sensors, data acquisition systems and sensor calibration**

NMSOP-2 presents an even more elaborated Chapter 5 on the basic theory of seismometry and the practice of instrument calibration and parameter determination. The theory is complemented by an extended Data Sheet 5.1 giving the essential parameters of two dozens of modern seismometer types, as well as by different exercises and links to freely available software for parameter determination and response calculations. NMSOP-2 introduces not only traditional inertial seismometers and strainmeters (IS 5.1), but for the first time also rotational sensors and rotation measurements (IS 5.3). In other chapters, the effects of different seismograph responses, post-record filtering or computational signal restitution on the appearance of seismograms and the reliability and reproducibility of parameter readings is demonstrated with many examples. Complementary to it, the updated Chapter 6 introduces the most recent developments and concepts of modern data acquisition systems.

Modern broadband seismographs record ground motions with a minimum of distortion and it is possible to restore true ground motion computationally with high accuracy. Seismic waveforms carry much more information about the seismic source and wave-propagation process than simple parameter readings of onset times, amplitudes and prevailing periods of seismic phases. Therefore, waveform modeling and fitting has now become a major tool both of advanced seismic research and increasingly also of routine processing and analysis. Seismic waveforms and amplitudes, however, strongly depend on the transfer function and gain of the seismograph, which must be known with high accuracy if the full potential of waveform analysis is to be exploited. Also reliable amplitude-based magnitude estimates, most of them still being determined from band-limited recordings, require accurate knowledge of the recording system's frequency-dependent magnification. Consequently, instrument parameters that control the instrument response must be known and kept stable with an accuracy of better than a few percent.

Unfortunately, at many seismic stations the seismographs have never been carefully calibrated, the actual gain and response shape is not precisely known and their stability with time is not regularly controlled. Some station operators rely on the parameters given in the data sheets of the manufacturers or those determined (possibly) by the primary installer of the stations. However, these parameters, instrumental gain in particular, are often not accurate enough. Therefore, station operators themselves should be able to carry out an independent, complete calibration of their instruments. For modern feedback-controlled broadband seismographs the basic parameters, eigenperiod and gain, are rather stable, provided that the seismometer mass is kept in the zero position. This, however, should be regularly controlled,

more frequently (e.g., every few weeks) in temporary installations and every few months in more stable permanent installations. Chapter 5 deals extensively with this issue and provides links to calibration software. Moreover, long-period seismographs are strongly influenced by the stability of the underground and installation platform. Variations in ambient temperature, air pressure fluctuations and other environmental disturbances may result in unwanted drifts and noise. Therefore, a new IS 5.4 deals specifically with the shielding and installation of broadband seismometers.

Although short-period instruments are generally considered to be much more robust and stable in their parameters, experience has shown that their eigenperiod and attenuation may change with time up to several tens percent, especially when these instruments are repeatedly deployed in temporary installations. Parameter changes of this order are not tolerable for quantitative analysis of waveform parameters. Therefore, more frequent control and absolute determination of these critical sensor parameters are strongly recommended after each re-installation.

#### **1.2.2.5 What has to be considered when installing new seismic networks?**

More and more countries now realize the importance of seismic monitoring of their territories for improved seismic hazard assessment and the development of appropriate risk-mitigation strategies. The installation and long-term operation of a self-reliant modern seismic network is quite a demanding and costly undertaking. Cost-efficiency largely depends on proper project definition, instrument and site selection based on a good knowledge of the actual seismotectonic and geographic-climatic situation, the availability of trained manpower and required infrastructure, and many other factors. Project-related funds are often available only within a limited time-window. Therefore, they are often spent quickly on high-tech hardware and *keys-in-hands* installations by foreign manufacturers without a careful site selection and proper allocation of funds for training and follow-up operation. If local people are not involved in these initial efforts and capable of using and maintaining these new facilities and data according to their potential, then the whole project might turn out to be a major investment with little or no meaningful return. These crucial practical and financial aspects are usually not discussed in any of the textbooks in seismology that mostly serve general academic education or research. Chapter 7, covering site selection, preparation and installation of seismic stations has therefore become, after adding 31 pages alone on seismic installations and observations in the marine environment, the second largest NMSOP-2 topic. Possible achievements using modern seismological networks, both physical and virtual ones, at local, regional and global scales, and their relation with respect to aperture, data processing and results to specialized seismic arrays, is extensively dealt with in Chapters 8, 9 and 14 of NMSOP-2.

### **1.3 Philosophy of the NMSOP**

The concept for the NMSOP was developed with consideration of the benefits and drawbacks of the old Willmore (1979) Manual, taking into account the technological developments and opportunities which have appeared during the last few decades, as well as the existing inequalities in scientific-technical conditions and availability of trained manpower world-wide (Bormann, 1994).

Seismological stations and observatories are currently operated by a great variety of agencies, whose staff consists of seismologists and technicians with widely varying training and interests, or with no staff at all and operated remotely from a seismological data or analysis center. They are equipped with hardware and software ranging from very traditional analog technology to highly versatile and sophisticated digital technology. While in industrialized countries the observatory personnel normally have easy access to up-to-date technologies, spare parts, infrastructure, know-how, consultancy and maintenance services, those working in developing countries are often required to do a reliable job with very modest means, without much outside assistance and usually lacking textbooks on the fundamentals of seismology or information about standard observatory procedures.

To ensure that data from observatories can be properly processed and interpreted under these diverse conditions, it is necessary to establish protocols for all aspects of observatory operation that may affect the seismological data itself. In addition, competent guidance is often required in the stages of planning, bidding, procurement, site-selection, installation of new seismic observatories and networks and the calibration of equipment so that they will later meet basic international standards for data exchange and processing in a cost-effective and efficient manner.

One drawback of the old Manual was that its chapters were organized purely according to components or tasks of observatory practice, namely:

- Organization of station networks;
- Instruments;
- Station operation;
- Record content;
- The determination of earthquake parameters;
- Reporting output;
- Macroseismic observations;
- International services.

A consequence of this structuring was that the seismological fundamentals required to understand the relevance and particulars of the various observatory tasks were sometimes referred to in various chapters and dealt with in a fragmented manner. This approach makes it difficult for observatory personnel to comprehend the interdisciplinary problems and aims behind observatory practice and to appreciate the related, often stringent requirements with respect to data quality, completeness, consistency of procedures etc. Further, this approach puts together in the same chapters basic scientific information, which is rather static, with technical aspects, which may change rapidly. This makes it difficult to keep the Manual up-to-date without frequent rewritings of entire chapters.

The IASPEI WG on the NMSOP agreed, therefore, to structure the new Manual differently:

- The body of the Manual should have a long-term character, outlining the scope, terms of reference, philosophy, basic procedures as well as the scientific-technical and social background of observatory practice. It should aim at creating the necessary awareness and sense of responsibility to meet the required standards in observatory work in the best interests of scientific progress and social service.
- The main body or backbone of the NMSOP should be structured in a didactically systematic way, introducing first the scientific-technical fundamentals underlying

each of the main components in the "information chain" (see Fig 1.2) before going on to major tasks of observatory work.

- This Manual core composed of thematic Chapters should be complemented by annexed material of complementary information, which can stand for itself. Some of these topics are too bulky or specific to be included in the body of the Manual, while others may require more frequent updating than the thematic Manual Chapters. Therefore, they should be kept separate and individualized. Some annexes give more detailed descriptions of special problems (e.g., event location or theory of source representation; seismic moment tensor and energy release calculations) others provide data about commonly-used Earth models, shareware for problem solving, seismic record examples, calibration functions for magnitude determination, widely-used sensors and their key parameters, or job-related exercises with solutions for specific observatory tasks such as phase identification, event location, magnitude estimation, fault-plane determination, complemented by a list of acronyms and a very detailed glossary of terms.
- While the printed first edition tried - for the sake of paper saving and cost reduction - to avoid any duplication throughout the Manual and therefore had an overall reference list and index, the electronic NMSOP-2 is more a compilation of stand-alone contributions. All are peer reviewed and have their own doi-number, overview listing of contents at the outset and a complete reference list at the end. They contain all essential information and illustrations required for understanding the problem or carrying out a specified task without the need to download or printout additional NMSOP material. Links and cross references to other NMSOP items or external sources of information mainly aim at stimulating further readings for the sake of justifying the statements made and/or deepening the understanding of the subject, as is the case of references in journal publications. This structuring also eases future independent upgrading of the MSOP contributions by the individual authors.

Thus, we hope to provide a new Manual which is a sufficiently complete, self-explanatory reference source ("cook and recipe book") aimed at providing awareness of the complexity of problems, basic background information, and specific instructions for the self-reliant execution of common "routine" or "pre-research" jobs by the technical and scientific staff at seismological stations, observatories, and network centers. This includes system planning, site investigation and preparation, instrument calibration, installation, shielding, data acquisition, processing and analysis, documentation and reporting to relevant national and international agencies, data centers or the public, and occasionally, also assessing and classifying earthquake damage.

The NMSOP will not cover the often highly automated procedures now in use at many international seismological data centers. These centers normally neither record nor analyze seismic records themselves, but rather use the parameters or waveforms reported to them by stations, networks or arrays. They usually have the expertise and the scientific-technical environment and international connections needed to carry out their duties effectively. Rather, the NMSOP mainly serves the needs of the majority of less experienced or too narrowly specialized operators and analysts in both developing and industrialized countries, so as to assure that all the necessary tasks within the scope and required standards for national and international data acquisition and exchange can be properly performed.

Worldwide there is no formal university education or professional training available for seismic station operators and data analysts. Observatory personnel usually acquire their training through “learning by doing”. The formal educational background of observatory personnel may be very different: Physicists, geologists, electronic or computer engineers, rarely geophysicists. Accordingly, the NMSOP tries to be comprehensible for people with different backgrounds, to stimulate their interest in interdisciplinary problems and to guide the development of their required practical skills. The method of instruction is mainly descriptive. Higher mathematics is only used where it is indispensable, e.g., in the seismometry chapter or in the information sheets about theoretical source representation (IS 3.1) and seismic moment tensor determination and decomposition (IS 3.9).

The NMSOP should, however, also be a contribution, at least in part, to public, high school and university education in the field of geosciences. Therefore, NMSOP-2 has been enriched by several new tutorials and quite many appealing animations on seismic rupture and ray propagation, event location, source radiation patterns, 3-D event-cluster presentation and its development in space and time. We hope that some of these components and practicals will be useful also for students of geophysics.

## 1.4 Contents of the NMSOP

The NMSOP has been made available in different forms:

- the first edition in 2002 as a loose-leaf collection of printed material in two volumes, complemented by a CD-ROM;
- the 1<sup>st</sup> slightly revised edition in 2009 (NMSOP-1) in electronic form as pdf-files on the Internet, accessible via <http://www.iaspei.org/projects/NMSOP.html> and <http://nmsop.gfz-potsdam.de>.
- the 2<sup>nd</sup> edition in electronic form only, accessible via the same websites and downloadable in all its components, as NMSOP-1 too. However, users with still insufficient or too slow internet connections may also request a NMSOP-2 DVD from the GFZ library ([bib@gfz-potsdam.de](mailto:bib@gfz-potsdam.de)).

### 1.4.1 The printed Manual (2002) and its electronic edition (NMSOP-1; 2009)

The IASPEI and ESC Working Groups for the NMSOP agreed on the following topical Manual chapters for the first edition (for details see List of Contents accessible via the websites <http://nmsop.gfz-potsdam.de> and <http://www.iaspei.org/projects/NMSOP.html>):

|            |                                                                                      |
|------------|--------------------------------------------------------------------------------------|
| Chapter 1: | Aim and scope of the IASPEI New Manual of Seismological Observatory Practice (NMSOP) |
| Chapter 2: | Seismic Wave Propagation and Earth Models                                            |
| Chapter 3: | Seismic Sources and Source Parameters                                                |
| Chapter 4: | Seismic Signals and Noise                                                            |
| Chapter 5: | Seismic Sensors and their Calibration                                                |
| Chapter 6: | Seismic Recording Systems                                                            |
| Chapter 7: | Site Selection, Preparation and Installation of Seismic Stations                     |
| Chapter 8: | Seismic Networks                                                                     |
| Chapter 9: | Seismic Arrays                                                                       |

- Chapter 10: Data Formats, Storage, and Exchange
- Chapter 11: Data Analysis and Seismogram Interpretation
- Chapter 12: Intensity and Intensity Scales
- Chapter 13: Volcano Seismology

These chapters form Volume 1 of the printed NMSOP and cover either the fundamental aspects of the main sub-systems of the "Information Chain of Seismology" as presented schematically in Fig. 1.2, or related specific tasks, technologies or methodologies of data acquisition, formatting, processing and application.

Volume 1 is complemented by Volume 2. The latter contains annexes in the following categories:

- **7 Datasheets (DS):** Lists of sensor parameters; record examples, travel-time curves, Earth models, calibration functions, etc.;
- **18 Information Sheets (IS):** They contain more detailed treatments of special topics or condensed summaries of special instructions/recommendations for quick orientation, present the standard nomenclature of seismic phase and magnitude names, give examples for parameter reports and bulletins, etc.;
- **14 Exercises (EX):** Practical exercises with solutions on basic observatory tasks such as event location, magnitude estimation, determination of fault-plane solutions and other source parameters, instrument calibration and response construction. For educational purposes, most of these exercises are carried out manually with very modest technical and computational means, however links are given to related software tools;
- **12 Program Descriptions (PD):** Short descriptions of essential features of freely available software for observatory practice and how to access it;
- **Miscellaneous:** A list of acronyms, an extensive index, the list of authors with complete addresses, an overall list of references for Volume 1 and a 28 page glossary of terms.

In total, NMSOP-1 comprises some 1250 pages.

### 1.4.2 The 2<sup>nd</sup> electronic edition (NMSOP-2; 2012-13)

All NMSOP-1 Chapters have been preserved in NMSOP-2, but significantly revised and/or amended. Four three Chapters have been added:

- Chapter 14: Investigation of Site Response in Urban Areas by using Earthquake Data and Seismic Noise
- Chapter 15: CTBTO: Goal, Networks, Data Analysis and Data Availability
- Chapter 16: Automated Event and Phase Identification

The 16 Chapters comprise already as many pages as the two volumes of NMSOP-1. An originally planned major new Chapter on "Seismological Contributions to Seismic Risk Mitigation", meant to become the crucial missing link to the engineering seismology, earthquake engineering, strong-motion recording, hazard and risk assessing and mitigating communities, could regrettably not be realized. It is hoped that this gap can at least partially be closed by related topical information sheets in future amendments to NMSOP-2 under a new editorship.

The number of information sheets (now 36), tutorials (5), exercises (16), and movie demonstrations (16 animations) has been greatly expanded in NMSOP-2, making for approximately another 850 pages, to which 200 pages of the currently most elaborate Glossary of terms in seismology, global and seismotectonics, engineering seismology and other related disciplines have been added. Thus, in total, NMSOP-2 will comprise about 2400 pages of material, complemented by many links to external sources.

## 1.5 Outreach of the NMSOP

The printed English version of the first edition of the NMSOP is meanwhile in use with some 2000 copies in more than 100 countries, complemented by another 2000 copies of a 2 volume book edition in Chinese and several 100 copies of partial translations into Russian, Indonesian and Turkish language, respectively. Accessibility and usage as well as the diversity of the user community will grow significantly with the two Internet editions now being available free of charge.

It is expected, therefore, that the user community of the NMSOP will not be limited to observatory personnel. Many chapters, sections, auxiliary materials and educational animations (for the latter see IS 1.1) will be of general interest to lecturers and students in seismology, geophysics or geosciences in general but also for increasingly popular courses of “seismology at schools” in many countries. Training institutions in the field of applied seismology may use any NMSOP-2 material, compiling training modules from it that are tailored to their specific requirements, provided that the data source and the individual authors of the related Manual contribution are properly cited (click on cover page: [Rights, Permissions, Acknowledgments and References to NMSOP-2](#), respectively NMSOP-1). Also, technical people from other disciplines might find (at least partially) useful pieces of information in the Manuals for their work and cooperation with seismologists such as disaster managers and risk mitigation planners. Thus NMSOP is hoped to be of long-term benefit to a rather diverse user community, including also those interested in historical approaches and results of observatory seismology.

Permanent maintenance and regular updating of NMSOP-2 will assure its wide and long-term outreach, in keeping with continuing developments and changing requirements. This will be a permanent duty of the IASPEI Commission on Seismological Observation and Interpretation (CoSOI) and its relevant Working Groups. The library of the GFZ German Research Centre of Geosciences will serve as the long-term host of the NMSOP website, assuring its presentation and maintenance according to international bibliographic and publishing standards, including the handling of all rights and permission affairs on behalf of IASPEI. Accordingly, the acting CoSOI chairman (see <http://www.iaspei.org/>) and the GFZ chief librarian, presently Mr. R. Bertelmann ([rab@gfz-potsdam.de](mailto:rab@gfz-potsdam.de)), are the two main focal points of contact in this grand international cooperative project. Related general questions and proposals should be addressed to them, in contrast to specific topical NMSOP-item inquiries and suggestions which should be addressed to the respective lead author.

## Acknowledgments

My thanks go to former members of the IASPEI Manual Working Group and all other authors who have actively contributed to the development of the Manual concept and the currently available drafts. Also acknowledged are the valuable comments and suggestions received on the original draft Chapter 1 from B. L. N. Kennett and S. A. Sipkin, which has now been amended and updated for the 2<sup>nd</sup> electronic edition NMSOP-2. The author is very grateful to P. Suhadolc and T. Meier for their very careful reviews of this new extended version of Chapter 1 and their valuable suggestions for improvement both content and language-wise.

## 1 Introduction

NMSOP-2 has been amended by many new materials, including demonstrations and animations to topical chapters, exercises, information sheets etc. Animations visualize in an appealing and easy comprehensible way key aspects outlined in the main texts. They are made freely available for viewing and downloading. These complementary materials are suitable for being used independently of NMSOP as a whole as educational material at different levels, e.g., for “seismology at schools”, which enjoys currently growing interest and support in many countries, in undergraduate university or on-the job training courses. Animation have proven to be useful and well received also by the audience in public lectures about Earth science including topics such as the nature and location of earthquakes by means of seismic recordings, the propagation of seismic waves through the Earth and their use for investigating the Earth structure. This is illustrated below by way of a several examples. IS 1.1 itself can be used as an introductory tutorial to the animations. With a view to a broad user spectrum we aim at a largely non-technical language and the introduction of all basic technical terms so that both this text and the animations can be understood also by interested pupil and layman.

The tutorials, demos and animations currently offered in NMSOP-2 are just a beginning. We sincerely hope that they will be further upgraded and significantly amended in future by additional ones on other topics, satisfying both specialized as well broader interests. Therefore, the Editor (first author) invites potential contributors to contact him and to make their related products available to the broad NMSOP user community. He will in turn arrange that these new contributions will be highlighted in and properly linked with the topically related NMSOP main texts, thus assuring their widest possible propagation and use.

## 2 Examples

### 2.1 Propagation of seismic rays through the Earth and the formation of seismic records

NMSOP-2 offers 10 animations which show the propagation of seismic rays of different seismic phases through the Earth as well as the formation of seismic records of these waves from earthquakes at different depth (from 10 to 600 km) at seismic stations of the German Regional Seismic Network (GRSN) or local networks at distances ranging from  $0.1^\circ$  to  $167^\circ$  (i.e., from about 10 km to over 18,000 km). These phases relate to both direct longitudinal (P) and transverse (S) body waves (see Figure 13) as well their (often multiply) reflected and/or converted versions. Rays are refracted, reflected and/or converted when interacting with velocity and density discontinuities or gradients in the Earth crust (e.g., the Conrad and Mohorovičić-discontinuity), or in the deeper Earth, such as the core-mantle boundary (see Figures 1 and 2).

Figure 3 shows a screen-shot of one of the seismic ray tracing and record animations for an earthquake in New Zealand, recorded at station MOX and other stations of the German Regional Seismic Network (GRSN) at epicentre distances between  $160^\circ$  and  $167^\circ$ . On the lower right a simplified Earth model with the mantle in turquoise, the outer core in lilac and the inner core in red. The generally gradual increase of seismic wave velocity with depth in the mantle causes the bending of the seismic rays and the strong decrease of wave velocity at the core-mantle boundary (CMB) from about 13 km/s in the lowermost mantle to 8 km/s in the uppermost core a pronounced refraction of the P waves into the core (see the turquoise ray). However, for rays that incident on the CMB at near vertical angles the refraction is negligible (see the dark blue ray through the inner core). Thus, the figure illustrates the dependence of the refraction angle on both the gradual (in the mantle) or discontinuous (CMB) change in velocity as well as on the incidence angle of seismic rays with respect to the velocity change with depth. And Figure 4 shows the currently best 1-D model AK 135 of velocity, density and attenuation related changes in the Earth according to Kennett et al. (1995) and Montagner and Kennett (1996). Such models have been derived by analyzing empirically determined travel-time curves of P, S and other seismic body waves as well as dispersion curves of surface waves.

**Figure 1** Simplified model of the crust showing ray traces of the main “crustal phases” observed in records of earthquakes at distances up to about 1000 km. The short term “Moho” stands for Mohorovičić-discontinuity. It is the boundary between the Earth crust and the Earth mantle, characterized by a strong increase in P-wave velocity from about 6.5 km/s to 8 km/s).

**Figure 2** **Top left:** Seismic rays through the Earth mantle (M), outer core (OC) and inner core (IC) with their respective phase symbols according to international nomenclature. Full lines: P-wave rays; broken lines: S-wave rays. **Top-right:** Related travel-time curves of these phases. **Red rays** relate to the seismic phases identified in a 3-component broadband seismogram recorded at station MOX, Germany (**bottom**), from an earthquake at a distance of 112.5° (compiled from various Figures in Chapter 2).

**Figure 3** Screenshot of a moment towards the end of the first animation example, based on seismic recordings of the Mw = 7.1 New Zealand earthquake of 21 August 2001 at stations of the German Regional Seismic Network (GRSN). For more explanation see text.

**Figure 4** The 1-D Earth model AK135. Seismic wave speeds according to Kennett et al., 1995), quality parameter  $Q$  and density according to Montagner and Kennett (1996).  $\alpha = v_p$  and  $\beta = v_s$  are the P- and S-wave velocity, respectively;  $\rho$  - density,  $Q_\alpha$  and  $Q_\beta = Q_\mu$  the “quality factor”  $Q$  for P and S waves. Note that wave attenuation is proportional to  $1/Q$ . The abbreviations on the outermost right stand, within the marked depth ranges, for: C – crust, UM – upper mantle, TZ – transition zone, LM – lower mantle, D'' - gradient layer, OC – outer core, IC – inner core. (Copy of part of Fig. 2.79 in Chapter 2).

The ray-propagation cartoon in Figure 3, and with better resolution Figure 5, shows that seismic rays, the deeper they penetrated into the Earth, the steeper they return back to the Earth surface. And the steeper they come to the surface the shorter are the time differences at which the respective seismic waves will arrive at different seismic stations on the surface. But the shorter the difference between the recorded phase arrivals the faster this wave - **apparently** - seems to travel along the surface. This apparent horizontal velocity  $v_{app}$  of the approaching wave front (see the bended curve in the middle insert of Figure 3 with the arrow in the direction of propagation) should not be mistaken as being the true wave velocity.  $v_{app}$  will become infinite for vertical incidence although the real velocity of P and S near to the Earth surface is not larger than about 5 km/s and 3 km/s, respectively. The inverse of  $v_{app}$  is called *slowness*  $= 1/v_{app}$ . The animation will show that surface-waves, travelling along the Earth surface (bended brown ray) with less than 3-4 km/s, are indeed the slowest waves of all. Also note that seismic rays do not travel only the shortest way from the source towards the recording stations but also the longer one. Accordingly, for the same type of wave, the respective long-path wavefront arrives later and from the opposite direction with *negative slowness*, i.e., they arrive first at the most distant stations and later at the nearer ones. This results in travel-time branches of different tilt (see the colored lines on the record plots of Figure 5 which connect the arrival times of the respective seismic phases.)

In the animation three kinds of seismic records are “written” as soon as the seismic waves of different phases, represented by their differently colored seismic rays, arrive at the stations. All three have been long-period filtered with the SRO-LP response which emphasizes periods around 20 s. The uppermost record section in Figure 3 (and more clearly in Figure 5) shows vertical-component records, the middle section transverse-component records and the lowermost

record section shows enlarged in amplitude and with better time resolution the first 15 min of the uppermost record. The T-component records only shear-wave motions in the horizontal plane.

**Figure 5** A modified version of Figure 3 with cleaner record and ray sections. For explanations see text.

By comparing these different records one can conclude:

- The first arriving longitudinal PKPdf waves (dark blue and steeply incident ray travelling through the inner Earth core), which oscillate in the direction of ray propagation, are best recorded on short-period vertical component records of high magnification. The same applies to the surface reflections of P (PP for the shorter way and PP2 for the longer opposite way of travel) and to PcPPKP.
- In contrast to P waves, shear waves, which oscillate perpendicular to the direction of propagation, can travel only through the Earth mantle and crust but not through the liquid outer core. They are best recorded in long-period horizontal component records. And if they contain only horizontally oscillating SH wave energy then they can be seen only in T-component records and not at all in the vertical component records. This applies to our record example to the SS phase (see the red ray and travel-time branch).
- If these arrival times increase with distance of the station to the earthquake than the seismic wave fronts arrive in our case from NNE (as for PKPdf, PP and SS), but if they decrease with distance then they arrive from the SSW (as for PP2, PcPPKP and PPP2).

Having understood these basic features of wave propagation, the formation of different seismic phases due to reflection and conversion, and their appearance in seismic records you may now enjoy the first animation by left-mouse click on the bold-blue file name [wendt.nz.qt](#) either here or by downloading it from the Directory [Download Programs and Files](#) (see link on the NMSOP-2 front page). Note that the file is very large and the download may take quite some time. Moreover, if you feel that for your purpose or comprehension the movie speed is either too fast or too slow try to catch the cursor running below the movie with a left-button mouse

click. Hold this button pressed and control the movie speed according to the time you need to read the texts and to comprehend the demonstration, or to speed up too slow sections. More explanations for all 10 movies are given in IS 11.3.

## 2.2 Wave front propagation, travel-time curves and location of near seismic events

Figure 6 is a simplified plot of the propagation of seismic wave fronts (blue circles for P waves and red circles for S waves) in a homogeneous Earth crust, i.e., a crust with constant velocity of wave propagation in all directions away from the seismic source (star). The source position at focal depth  $h$  below the Earth surface is termed the hypocenter  $H$  and its projection on the surface the epicenter  $E$ . Accordingly, the distance on the Earth surface between the epicenter  $E$  and the recording station is termed epicenter distance  $D$  and the straight line distance between the hypocenter and the station the hypocenter distance  $R$ .

**Figure 6** Simplified plot of wave propagation from a seismic source in a homogeneous Earth crust and explanation of terms for characterizing source position and station distance.

The animation shows:

- that in the case of such simplified assumptions about the crustal velocity model the wavefronts of P and S propagate as expanding circles, both in the vertical plane through the source (star) and in the horizontal plane around the epicenter;
- how the seismic records are written on several seismic station sites as soon as the wave fronts arrive,
- how different the amplitudes and amplitude ratios between the first arriving P waves and the later following S waves may look like in the seismic records, and
- how the travel-time curves of P and S as a function of epicenter distance  $D$  are formed according to the arrival times of the P and S waves.

This is illustrated in Figure 7 by three screen shots of the movie, taken at different times. The rather smoothly bended travel-time curves shown in the lower row of Figure 7 for P and S waves are average curves for the area assuming a homogeneous crustal velocity model and a source depth of 12.1 km. In contrast, the light colored straight-line curves relate to a source depth of zero kilometers. The onset times for P and S in real records at the different stations may differ up to several tenths of seconds from the theoretical ones due to velocity inhomogeneities in the different directions of wave propagation. When drawing the travel-time curves through the really observed onset times of P and S, these curves would look rather “bumpy”, and accordingly the circular wave fronts in the middle and upper row of the screen shots as well. Event location algorithms are based on the least-square minimization of

the difference between observed arrival times of seismic phases and calculated arrival times based on average velocity models. However, without prior detailed investigations we usually do not know much better the real velocity distribution. Then one has to work with the simplified model of circular wavefront propagation. But we should be aware of the possible range of related uncertainties of the location results. They also depend on the number and distance of available recording stations with respect to the seismic source. If, however, we have already a rather detailed knowledge about the 3-D distribution of velocity inhomogeneities by tomographic or other investigations then the number of data to be taken into account in calculating the source location would increase with the third power. Handling such data requires huge data storage and super high-speed data processing facilities. But our tutorial and related animation demonstrates that even with simplified assumption reasonably good seismic source locations can already be made by applying a **circle and chord method**, which can be performed even by hand (for details see EX 11.1).

**Figure 7** Screen shots of the movie about P- and S-wave propagation from a small earthquake in Germany with magnitude  $M_l = 1.7$ , recorded in the local distance range up to 20 km. **Upper row:** Horizontal circular expansion of the of P (blue) and S (red) wavefronts and the related short-period seismic records at stations of a local seismic network. Note the strong variation of the amplitude ratio between P and S waves at different stations. **Middle row:** Vertical circular expansion of the P and S wavefronts. **Lower row.** Light blue and red linear curves: Theoretical travel-time curves for P and S waves from a source at depth  $h = 0$  km; dark blue and red: theoretically expected travel-time curves for P and S waves radiated by a source at 12.1 km depth, superimposed by short-period records at seismic stations as a function of epicenter distance. Download and activate the movie by left-mouse click on the file name [3D-wave-prop travel-time qt.](#)

For carrying out the circle and chord exercise one has to know that longitudinal P waves travel roughly  $\sqrt{3}$  times faster than transverse S waves. Further that in continental areas the crustal thickness is on average about 30-35 km thick. For shallow crustal earthquakes Pg is then the first arriving longitudinal wave and Sg the first arriving transverse wave up to distances of about 5 times the crustal thickness (see Figure 1). The difference of arrival times,  $t(Sg - Pg)$  measured in seconds, increases more or less linear with hypocenter distance R in kilometers according to the relationship

$$R = t(Sg - Pg)[(v_p \cdot v_s) / (v_p - v_s)].$$

R can thus roughly be estimated when  $v_p$  and  $v_s$  are known. Assuming for Pg in a homogeneous crust a constant average velocity  $v_p = 5.9$  km/s and thus for Sg of  $v_s \approx v_p / \sqrt{3} \approx 3.4$  km/s then  **$R \approx 8 \times t(Sg - Pg)$** . This is the commonly assumed “rule-of-thumb”. However, for events in the region considered in Figure 7  $v_p = 6.2$  km/s yields better locations. Accordingly,  $R = 8.3 \times t(Sg - Pg)$  would then be more appropriate.

For  $h > 0$  R is generally larger than the epicenter distance.  $R = D$  holds only for either  $h = 0$  or  $D \gg h$  ( $\rightarrow$  asymptotic approximation).

Measuring  $t(Sg - Pg)$  on records of at least 3 stations allows a rough source location by drawing circles with radii  $R_i$  around the stations. However, since for  $h > 0$  km  $D < R$  the circles do not intersect at the epicenter but overshoot. Only their chords, i.e., the straight lines connecting the two overcrossings between different pairs of circles (Figure 8 right) intersect close to the epicenter.

**Figure 8 Left:** Average linear travel-time curves for P and S from a surface source ( $h = 0$  km) in the Vogtland swarm earthquake region in the South of Eastern Germany and their best match with 3 seismic records at stations of the local Vogtland network at epicenter distances of 16.7, 17.7 and 19.0 km, respectively. **Right:** Circles drawn around the stations with the radii according to the epicenter distances estimated from the left-hand diagram, together with the three chords drawn between the crossing points of overshooting circle. The chords intersect close to the epicenter.

When matching the onset times of the Pg and Sg wave groups recorded at three stations in the near source area with the average linear travel-time curves for P and S waves from a surface source one would estimate epicenter distances of 16.7, 17.7 and 19.0 km, respectively (Figure 8 left). When drawing circles with these radii around the respective stations they strongly overshoot. The circle overshoot, however, is a strong indicator for a finite source depth, which is the deeper the larger the overshoot. By step-wise increase of  $h$ , the calculated epicenter distance radii  $d_i$  decrease (see Figure 9) until for  $d_{i \min}$  the “true” (better: the most likely) source depth  $h_{\text{true}}$  can approximately be estimated via the relationship

$$d_{i \min} = (R_i^2 - h_{\text{true}}^2)^{-2}.$$

The circles drawn around the stations  $i$  with  $d_{i \min}$  for “ $h_{\text{true}}$ ” are expected to have minimum overshoot (see Figure 9), provided that the wave propagation conditions are sufficiently homogeneous and well represented by the assumed velocity model, and further, that the reading errors of phase onset times on the station records are negligible.

For seeing and downloading the whole movie click with the left mouse button on the file name [wendt waveprop circles](#) either here, or in the list of [Download programs and files](#).

**Figure 9** The minimum circle overshoot is achieved for “ $h_{\text{true}}$ ” = 13.5 km, corresponding to circle radii of epicenter distances of 9.8, 11.4 and 13.4 km, respectively.

### 2.3 Presentation of earthquake sequences in their space-time-magnitude development

Earthquake swarms and aftershock sequences of large earthquakes may consist of hundreds to thousands of events within a limited area, occurring within a relatively short time span with more or less clear spatial relationship to the activated regional seismotectonic features. Moreover, sometimes such sequences are characterized by specific event-number-magnitude-

frequency time plots (Figure 10) and may also show pronounced spatial migration. In order to facilitate a well structured comprehensive analysis of such a multitude of features suitable forms of data presentation are highly desirable, both in the form of 2-D diagrams or projections of 3-D hypocenter clouds as well as their viewing from different perspectives.

**Figure 10** Local magnitude MI frequency of occurrence of swarm and individual earthquakes in the Vogtland/Germany (dots) and Western Bohemia/Czechia (triangles) region (see Figure 11) between January 1, 2007, and Dezember 31, 2011. Different colors relate to different subregions. Total number of earthquakes 5392.

The animation illustrates this by way of example of an earthquake swarm that occurred between October and December 2008 in Western Bohemia/Czechia. Figure 11 shows the wider area of this source region and the inserted box frame delimitates the area of the specific swarm dealt with in our animation. The total number of detected events in this swarm was 8500 in the magnitude range  $-1 < MI < 4$ . The epicenters fall within an area of only some 6 km in length and 1.5-2.5 km in width. During this swarm a south-to-northward migration of the foci has been observed with gradually decreasing focal depth from initially about 9.5 km to 4.5 km and slight changes in the dominating strike and dip direction of the activated local fault system as inferred from the cumulative clustering of hypocenters (see Figure 12).

To ease the comprehension of these developments in time, the epi- and hypocenters have been assigned different color, ranging from dark blue in early October to bright red in late December 2008 and then been projected to vertical cut planes through the 3-D event cloud along different profiles. The size of the event circles differs with magnitude. The dominating strike direction of the activated fault system can be inferred from the main axis through the epicentre cloud and the related fault dip from the main axis of the best aligned hypocenter projection plot. The latter can best be found by “walking around” the source area and looking at vertical profile projections from different view angles (see open arrow in the animation).. The animation illustrates this. Activate and/or download the movie by left-button-mouse click on the bold-blue file name [\*\*wendt source migra around\*\*](#) either here or in the listing of [Download programs and files](#), which can be opened via *overview* on the front page of NMSOP-2.

**Figure 11** Epicenter map of the earthquake region Vogtland/Germany and Western Bohemia/Czechia. The inserted box in the lower right part delimitates the area of the earthquake swarm in Czechia between October and December 2008 in Figure 10.

**Figure 12** **Left:** Epicenter plot of the earthquake swarm. **Upper right:** hypocenters projected to the vertical plane of the near E-W profile in the epicentre plot. **Lower right:** Event-number-magnitude development with time for MI > 1.5 (during October), respectively MI > 0 during November and December 2008.

In summary, the respective data plots yield a kind of regional cumulative fault plane solution for the earthquake swarm as a whole or of its sub-phases in time. For the main phase in October 2008 the inferred strike direction of the activated fault system is about  $168^\circ$  from North and the fault dip is about  $70^\circ$  towards west. The average strike direction for the total swarm was about  $174^\circ$  with a dip of  $63^\circ$ .

## 2.4 Radiation patterns of earthquake fault mechanisms

In the event of an earthquake the two adjacent rock formations on both sides of the earthquake fault move relatively to each in opposite direction (see Figure 14, the open arrows). The released elastic strain energy generates both near-source kinematic energy, and the kinematic energy in the source region that propagates as seismic waves to the far field. The seismic waves consist of longitudinal motions in the direction of wave propagation (P waves) and transverse motions perpendicular to the direction of wave propagation (S waves). In the case of S waves the transverse motion may be separated into two components, namely motion in the vertical plane, as in Figure 13, termed SV, and those in the horizontal plane, termed SH.

**Figure 13** Displacement patterns of a harmonic plane P wave (top) and SV wave (bottom) propagating in a homogeneous isotropic medium.  $\Lambda$  is the wavelength and  $2A$  means double amplitude. The white surface on the right is a segment of the propagating plane wavefront where all particles undergo the same motion at a given instant in time, i.e., they oscillate *in phase*. The arrows indicate the seismic rays, defined as the *normal* to the wavefront, which points in the direction of propagation. (Copied from Fig. 2.6 in Chapter 2, modified according to Shearer, Introduction to Seismology, 1999; with permission from Cambridge Univ. Press).

Earthquake shear ruptures show a typical radiation pattern, which is different for P and S waves. These patterns are characterized by so-called amplitude lobes, i.e., by azimuth-dependent radiation of amplitudes, respectively energy. In the case of a pure shear rupture in a homogeneous isotropic medium P-waves have the smallest (idealized zero) amplitudes in the direction of fault rupture and the largest amplitudes (see black arrows in Figure 11, left side) at an angle  $45^\circ$  off the fault plane whereas shear (S) waves have the largest amplitudes in the direction of the shear rupture and perpendicular to it. Joint analysis of P and S wave amplitudes, and especially of the amplitude ratios of P/SV and P/SH, is – although a quite complicated procedure – a powerful method to identify the type of earthquake rupture, to reliably constrain its orientation in space and to quantify its defining parameters with an even

smaller number of observations points and less complete azimuthal coverage than required when only P-wave first motion polarities are used.

**Figure 14** Diagrams of the radiation pattern of the radial displacement component of P-waves (left) and of the transverse displacement component of S waves (right) from a double couple shear rupture (Modified combination of Figures 4.5 and 4.6 of Aki and Richards, 2002; with permission of P. Richards).

One recognizes from Figure 14 (left-hand panel) that the longitudinal source displacement is outward directed in the upper right and lower left quadrant. Accordingly, the related P waves arrive at seismic stations as a compression signal which produces in vertical component records an upward first motion (+). In contrast, in the two other quadrants, 90° away from the + quadrants, the longitudinal displacement is directed towards the source (dilatation). Accordingly, the P-wave first motion in vertical component records is downward (-). Therefore, the most simple and most frequently used method of determining the seismic source mechanism is to investigate the azimuthal distribution of first motion polarities observed at seismic stations surrounding the seismic source in all directions (see EX 3.2). However, small earthquakes are commonly recorded in narrowband filtered seismic records of high magnification. Due to the rather pronounced transient response of such records the first motion amplitudes may be significantly smaller than the largest amplitudes in the P waveforms and be distorted or even buried in the seismic noise (see Chapter 4, Figs. 4.9 and 4.10 and Chapter 16, Fig. 16.25). Therefore, one requires many more and azimuthally well distributed P-wave polarity readings than P/S wave amplitude ratios in order to produce a well constrained fault plane solution. Also, maximum amplitudes in the P- and S-waveforms can still reliably be read if the P-wave first motion is already buried in the noise.

According to Figure 14 a fault which ruptures perpendicular to the horizontally plotted fault rupture would produce the same radiation pattern. Therefore, analyzing only P-wave polarity distributions will not allow to say, which of the two possible faults has really ruptured. Therefore, in this kind of an idealized point source rupture model according to a double-couple shear force system (see black arrows in the right S-wave panel of Figure 14) the amplitude radiation lobes have been symmetrically mirrored. Yet, this ambiguity which of the two potential fault planes is really the acting one is a principle one, independent on whether one analyzes the P- or S-wave radiation pattern or that of the P/S-wave amplitude ratios. In practice it can only be resolved by assessing either the directivity effects (see Figure 19 and related comments), or the distribution of aftershocks, or by invoking geological information (tectonic setting, mapped faults; see solutions of EX 3.2).

The key parameters which control the orientation and slip of a fault in space and thus the observed radiation pattern of P- and S-wave amplitudes are (see Figure 15):

- strike angle  $\phi$  (measured clockwise from north);
- dip angle  $\delta$  (measured downwards from the horizontal);
- rake angle  $\lambda$ , which describes the slip direction (values between  $0^\circ$  and  $180^\circ$  for upward motion or between  $0^\circ$  and  $-180^\circ$  for downward motion of the hanging/overlying wall).

**Figure 15** Idealized rupture plane with slip lineations surrounded by an imagined so-called “focal sphere” centered in the origin. **Top:** upper hemisphere, **middle:** lower hemisphere; **bottom:** projection of the lower focal hemisphere fault plane onto the horizontal plane between the two hemispheres. The block of the Earth medium above the fault plane is termed the “hanging wall”, that below the “foot wall”.

According to the relationship between these three fault-plane parameters one classifies earthquake ruptures into 3 basic types and related mixed types. In seismological publications they are usually presented as the projections of the fault plane cut traces through the focal sphere onto the horizontal plane between the upper and lower focal hemisphere and by coloring or shading differently the quadrants with compressional and dilatational first P-wave motions. Such presentations of fault plane solutions are also nick-named as “beach-ball solutions” (see Figure 16).

**Figure 16** **Top:** Simplified models of block motion in the case of pure normal faulting, strike slip faulting and thrust faulting; **Right:** “Beach-ball” presentations of basic and mixed types of faulting. (Courtesy of Michael Baumbach †, 2001)

As compared to Figure 14, the amplitude radiation patterns for P and S waves observed on the Earth surface from earthquake ruptures with different fault-plane and slip orientation in space are rather asymmetric. This could be shown for a well constrained fault plane solution of a Vogtland earthquake in Germany with known strike, dip and rake. The radiation lobes (also for the animation examples) have been calculated by using the formulas (4.89) to (4.91) published by Aki and Richards (2002). No assumptions with respect to *source directivity*, rupture velocity or type of slip (e.g., unilateral, bi-lateral, circular) have been made (see final discussion below). The agreement with the actually recorded amplitude ratios measured at stations of a local network is remarkably good. E.g., for the station TRIB the calculations predict for PV a very small amplitude but a slightly larger SV amplitude. In contrast, as observed, PV should be larger than SV for station GUNZ (Figure 17). This concerns the expected amplitude ratios, not the absolute amplitudes. The latter additionally depend on epicenter distance, local site amplification effects and other factors.

**Figure 17** Comparison of theoretically calculated radiation patterns for an earthquake with well constrained fault plane solution and slip direction with the really observed amplitude ratios between vertical component P and S amplitudes at stations of a local seismic network in Germany. The source depth of the earthquake has been 12.1 km and the epicenter (respectively hypocenter) distances of stations GUNZ and TRIB were 5.8 km (13.4 km) and 8.5 km (14.7 km).

The azimuth-dependent PV, SV, SH amplitude lobe patterns depend on the **strike, dip and rake** and thus on the type of source mechanism of the acting fault plane. But with respect to the seismic stations which record these amplitudes the lobe size and patterns also depend on the incidence angle of the seismic rays. This is shown with the first animation, while in the following animations, which demonstrate the effect of variations in dip and rake, the incidence angle at the recording stations has been kept fixed. The movie with several of such

animations can be viewed and/or downloaded by left mouse-button click on the file name [wendt\\_source\\_rad\\_pat](#) either here or in the listing [Download programs and files](#). After downloading Linux users should activate the movie by typing after the command **xanim** the file name **wendt\_source\_rad\_pat**. Figure 18 presents two snap shots from this movie.

**Figure 18** Cut-out scenes of the movie [wendt\\_source\\_rad\\_pat](#) for dip and rake variations.

In all these calculations, source directivity has been neglected. According to the NMSOP-2 Glossary, the term **directivity** is defined as: “An effect of a propagating fault rupture whereby the amplitudes and frequency of the generated ground motions depend on the direction of wave propagation with respect to fault orientation, slip direction(s) and rupture velocity  $v_r$ . The directivity and thus the radiation pattern is different for P and S waves.” It becomes more pronounced when  $v_r$  approaches the respective wave velocity. Accordingly, it is larger

for S than for P waves. This is illustrated by Figure 19.  $v_R$  commonly ranges between about 0.2 and 0.9 times of the shear-wave velocity  $v_s$  (Venkataraman and Kanamori, 2004b). Yet, in rare cases, it may even exceed  $v_s$  if the hypothesis and still debated occasional observational evidence of supershear slip pulses with rupture velocities up to 5 km/s really holds (e.g., Bouchon and Vallée, 2003).

**Figure 19** Variability of P- and SH-wave amplitude for a fault rupture propagating unilaterally from left to right with  $v_R/v_s = 0.5$  (left column) and  $v_R/v_s = 0.9$  (right column), respectively.

(From Kasahara, 1981; © Cambridge University Press).

In the directions of enlarged amplitudes the recorded broadband pulse width of P and S (or source time function) is compressed, in the directions of reduced amplitudes, however, stretched, i.e., the apparent rupture duration is azimuth dependent. Yet the area underneath the pulses, which is proportional to the seismic moment of the fault rupture, remains constant, i.e., it is independent on the azimuth of observation.

Pronounced directivity effects are observed for extended (finite linear in contrast to point source) ruptures of strong earthquakes, primarily in the case of unilateral rupture propagation. The azimuthal effects, however, are much less in the case of bilateral ruptures and disappear in the case of circular ruptures. Only in rare cases the effects of vertical directivity have been observed. (See related discussions and Figures in Lay and Wallace, 1995). The frequency dependence is due to the Doppler-effect. It can be quantified by investigating the azimuth-dependence of the frequency spectra of the recorded P and S waves. Thus, in the case of distinct directivity effects one can unambiguously identify, which of the two potential rupture planes has really moved.

For small local events, however, recorded at rather high frequencies, directivity effects can usually be neglected. E.g., in the case of the earthquake in Figure 17 with  $M_l = 1.7$  the source radius has been estimated to be about 0.1 km only, when assuming a circular rupture according to the Brune (1970) or Madariaga (1976) models (see EX 3.4). Moreover, according to Cho et al. (2010), observations suggest that directivity effects are generally present only at frequencies less than about 1 Hz, whereas the records presented in Figure 17 consist only of frequencies above 6 Hz. At high frequencies, the directivity effect is generally reduced and the radiation pattern observed in the far-field (i.e., at distances of several wavelengths, as in our case) changes from the usual double-couple pattern as in Figure 14 to a more isotropic one. Such differences in the radiation patterns between high and low frequency

ground motion have already earlier been explained as either a source effect (with real sources losing coherence at short wavelengths associated with source roughness/irregularities that are not considered in planar fault models) or as a multi-pathing effect (with high frequency waves being preferentially scattered by crustal heterogeneities (e.g., Newmann and Okal, 1998) or a combination of both (Bormann and Di Giacomo, 2011)).

In summary, if spatially extended earthquakes do not, as in Figure 19, propagate unilaterally but bilateral or in an even more complex manner (as, e.g., the Chile earthquake 2010 in section 2.6), radiation patterns may look different from those presented here. They may even vary with time during great ruptures that last for several minutes.

## 2.5 Rupture tracking of the great 2004 Mw9.3 Sumatra-Andaman earthquake

This is a pure movie without accompanying text. It illustrates the variability of energy release in space and time by great earthquake ruptures which can not be described by a point source or otherwise simplified rupture models. The movie has kindly been made available by Matthias Ohrnberger. It relates to the publication in *Nature* by Krüger and Ohrnberger (2005) about rupture tracking of the great 26 December 2004 Sumatra-Andaman tsunamigenic earthquake by using the German Regional Seismic Network as a large-scale teleseismic array (see Figure 20). The movie illustrates that such a great earthquake with variable rupture trend, rupture velocity and energy release in different rupture segments can really not be described reasonably well by a common single source fault-plane solution. Tsai et al. (2005) have later approximated this earthquake by a more realistic multi source rupture with 5 major sub-sources.

**Figure 20** **Left:** Ray paths from the source area of the Sumatra-Andaman earthquake to Germany and, in the insert, the outlay of stations of the German Regional Seismic Network (GRSN) that has been used as a large-scale teleseismic array for tracking the rupture. **Right:** Rupture propagation as a function of time with the radius of the circles being proportional to the seismic energy released. Combined Figures 1 and 3 of Krüger and Ohrnberger (2005), *Nature*, 435, p.937 and 938; doi: 10.1038/nature0396 (© Copyright Clearing Centre of Nature).

For activating and/or downloading of the movie click with the left mouse button on the file name [ohrnberger sumatra2004 rupture](#) proceed as described above.

## 2.6 Rupture tracking of the great 2010 Mw8.8 Chile earthquake

A similarly strong damaging earthquake occurred in Chile on 27 February 2010. Its rupture process has been tracked by Yanlu Ma of the GFZ German Research Centre for Geosciences by applying a similar procedure described by Krüger and Ohrnberger (2005). He used travel-time delays observed at North American seismic stations, mainly of the USArray, yet including some other permanent stations, e.g., of the California network, as well.

In contrast to the Sumatra earthquake, which can be described as a unilateral rupture, the centers of large seismic energy release during this Chile earthquake jump forth and back, making it to a multilateral rupture. This animation illustrates well how irrelevant in such a case parameters such as epicenter location, average displacement, average stress drop, average rupture velocity or similar are with respect to assessing the hazard posed by such an extended earthquake rupture.

**Figure 20** Map of area of the great Chile earthquake of 2010. Blue dots: epicentres of aftershock within the first few days. Red star: epicentre of the main shock. The colored areas cover the 95% confidence region of seismic energy release of major sub-events of this complex rupture.

Activate/download this movie with the left-button mouse click on the file name [gfz ma chile2010 rupture](#) here or in the directory *Download programs and files* (see overview on the NMSOP-2 front page).

## Acknowledgments

We acknowledge with gratitude the animations and figures made available by Matthias Ohrnberger, University of Potsdam, and of Yanlu Ma, GFZ Potsdam, Germany, for sections 2.5 and 2.6. as well as the use of Figures produced by late Michael Baumbach †, GFZ Potsdam, for Chapter 3 of NMSOP-1 (2002) which enabled us to compile Figure 16. We also thank Paul Richards for extensive clarifying discussions and helpful comments on matters discussed in section 2.4. and for permitting the compilation of Figure 14 based on Figures 4.5 and 4.6 in Aki and Richards (2002).

## 2.1 Introduction (P. Bormann)

The key data to be recorded by means of *seismic sensors* (Chapter 5) and *recorders* (Chapter 6) at seismological observatories (*stations* – Chapter 7, *networks* – Chapter 8, *arrays* – Chapter 9) are *seismic waves*, radiated by *seismic sources* (Chapter 3). Weak signals may be masked or significantly distorted by *seismic noise* (Chapter 4), which is usually considered disturbing and unwanted. Only in some special engineering-seismological applications is seismic noise also appreciated as a useful signal, from which some information on the structure, velocity and fundamental resonance frequency of the uppermost sedimentary layers can be derived (Chapter 14). But most of what we know today of the structure and physical properties of our planet Earth, from its uppermost crust down to its center, results from the analysis of seismic waves generated by more or less localized natural or man-made sources such as earthquakes or explosions (Chapter 3, Figs. 3.1 to 3.4) by either (repeatedly) solving the so-called forward (direct) or the inverse problem of data analysis (Chapter 1, Fig. 1.1).

It is not the task of the New Manual of Seismological Observatory Practice (NMSOP), to provide an in-depth understanding of the theoretical tools for this kind of analysis. There exist quite a number of good introductory (Lillie, 1999; Shearer, 1999) and more advanced textbooks (e.g., Aki and Richards, 1980, 2002 and 2009; Ben-Menahem and Singh, 2000; Bullen and Bolt, 1985; Dahlen and Tromp, 1998; Lay and Wallace, 1995; Kennett, 2001), and a variety of monographs, overview and special papers related to specific methods (e.g. Fuchs and Müller, 1971; Červený et al., 1977; Kennett, 1983; Müller, 1985; Červený, 2001; Chapman, 2002), types of seismic waves (e.g., Malischewsky, 1987; Lapwood and Usami, 1981; Kanamori, 1993; Lognonné and Clévéde, 2002; Romanovicz, 2002; Kennett, 2002) or applications (e.g., Gilbert and Dziewonski, 1975; Sherif and Geldart, 1995; Cara, 2002; Curtis and Snieder, 2002; Minshull, 2002; Mooney et al., 2002; Nolet, 1987 and 2008; Song, 2002; Kanamori and Rivera, 2008; Hayes et al., 2009). Rather, we will take here a more phenomenological approach and refer to related fundamentals in physics and mathematical theory only as far as they are indispensable for understanding the most essential features of seismic waves and their appearance in seismic records and as far as they are required for:

- Identifying and discriminating the various types of seismic waves;
- Understanding how the onset-times of these phases, as observed at different distances from the source, form so-called travel-time curves;

- Understanding how these curves and some of their characteristic features are related to the velocity-structure of the Earth and to the observed (relative) amplitudes of these phases in seismic records;
- Using travel-time and amplitude-distance curves for seismic source location and magnitude estimation;
- Understanding how much these source-parameter estimates depend on the precision and accuracy of the commonly used 1-D Earth models (see IS 11.1);
- Appreciating how these source parameter estimates may be improved by using more realistic (2-D, 3-D) Earth models as well as later (secondary) phase onsets in the processing routines; and
- Being aware of the common assumptions and simplifications made in synthetic seismogram calculations that are increasingly used nowadays in seismological routine practice (see 2.5.4.4; 2.8; 3.5.3).

## 2.2 Elastic modules and body waves (P. Bormann)

### 2.2.1 Elastic modules

Seismic waves are elastic waves. Earth material must behave elastically to transmit them. The degree of elasticity determines how well they are transmitted. By the pressure front expanding from an underground explosion, or by an earthquake shear rupture, the surrounding Earth material is subjected to *stress* (compression, tension and/or shearing). As a consequence, it undergoes *strain*, i.e., it changes volume and/or distorts shape. In an inelastic (plastic, ductile) material this deformation remains while elastic behavior means that the material returns to its original volume and shape when the stress load is over. There exist also materials with elastic-plastic behavior.

The degree of elasticity/plasticity of real Earth material depends mainly on the *strain rate*, i.e., on the length of time it takes to achieve a certain amount of distortion. At very low strain rates, such as movements in the order of mm or cm/year, it may behave ductile. Examples are the formation of geologic folds or the slow plastic convective currents of the hot material in the Earth's mantle with velocity on the order of several cm per year. On the other hand, the Earth reacts elastically to the small but rapid deformations caused by a transient seismic source pulse. Only for very large amplitude seismic deformations in soft soil (e.g., from earthquake strong-motions in the order of 40% or more of the gravity acceleration of the Earth) or for extremely long-period free-oscillation modes (see 2.4) one has to take the inelastic non-linear response of the otherwise more or less solid Earth's material into account.

Within its elastic range the behavior of the Earth material can be described by *Hooke's Law* that states that the amount of strain is linearly proportional to the amount of stress. Beyond its elastic limit the material may either respond with brittle fracturing (e.g., earthquake faulting, see Chapter 3) or non-linear ductile behavior/plastic flow (Fig. 2.1).

**Fig. 2.1** Schematic presentation of the relationship between stress and strain.

Elastic material resists differently to stress depending on the type of deformation. It can be quantified by various elastic modules:

- The *bulk module*  $\kappa$  is defined as the ratio of the hydrostatic (homogeneous all-sides) pressure change to the resulting relative volume change, i.e.,  $\kappa = \Delta P / (\Delta V/V)$ , which is a measure of the *incompressibility* of the material (see Fig. 2.2 top);
- The *shear module*  $\mu$  (or “*rigidity*”) is a measure of the resistance of the material to shearing, i.e., to changing the shape and not the volume of the material. Its value is given by half of the ratio between the applied shear stress  $\tau_{xy}$  (or tangential force  $\Delta F$  divided by the area  $A$  over which the force is applied) and the resulting shear strain  $e_{xy}$  (or the shear displacement  $\Delta L$  divided by the length  $L$  of the area acted upon by  $\Delta F$ ), that is  $\mu = \tau_{xy}/2 e_{xy}$  or  $\mu = (\Delta F/A) / (\Delta L/L)$  (Fig. 2.2 middle). For fluids  $\mu = 0$ , and for material of very strong resistance (i.e.  $\Delta L \rightarrow 0$ )  $\mu \rightarrow \infty$ ;
- The *Young’s module*  $E$  (or “*stretch module*”) describes the behavior of a cylinder of length  $L$  that is pulled on both ends. Its value is given by the ratio between the extensional stress to the resulting extensional strain of the cylinder, i.e.,  $E = (F/A) / (\Delta L/L)$  (Fig. 2.2 bottom);
- The *Poisson’s ratio*  $\sigma$  is the ratio between the lateral contraction (relative change of width  $W$ ) of a cylinder being pulled on its ends to its relative longitudinal extension, i.e.,  $\sigma = (\Delta W/W) / (\Delta L/L)$  (Fig. 2.2 bottom).

**Fig. 2.2** Deformation of material samples for determining elastic modules. Top: bulk module  $\kappa$ ; middle: shear module  $\mu$ ; bottom: Young's module  $E$  and Poisson's ratio  $\sigma$ . a – original shape of the volume to be deformed; b – volume and/or shape after adding pressure  $\Delta P$  to the volume  $V$  (top), shear force  $\Delta F$  over the area  $A$  (middle) or stretching force  $F$  in the direction of the long axis of the bar (bottom).

Young's module, the bulk module and the shear module all have the same physical units as pressure and stress, namely (in international standard (SI) units):

$$1 \text{ Pa} = 1 \text{ N m}^{-2} = 1 \text{ kg m}^{-1} \text{ s}^{-2} \quad (\text{with } 1 \text{ N} = 1 \text{ Newton} = 1 \text{ kg m s}^{-2}). \quad (2.1)$$

## 2.2.2 Stress-strain relationships and equation of motion

The most general linear relationship between stress and strain of an elastic medium is governed in the generalized *Hook's law* (see Equation (10) in the IS 3.1) by a fourth order parameter tensor. It contains 21 independent modules. The properties of such a solid may vary with direction. Then the medium is called *anisotropic*. Otherwise, if the properties are the same in all directions, a medium is termed *isotropic*. Although in some parts of the Earth's interior anisotropy on the order of a few percent exists, isotropy has proven to be a reasonable first-order approximation for the Earth material as a whole. The most common models, on which data processing in routine observatory practice is based, assume isotropy and changes of properties only with depth (1-D models; see 2.7.1). Yet, advanced tomographic procedures of seismic travel-time and waveform analysis allow nowadays deriving also 3D-models of the Earth material from local to global scale (see, e.g., 2.7.2; Nolet, 1987; Curties and Snieder, 2002).

In the case of isotropy the number of independent parameters in the elastic tensor reduces to just two. They are called after the French physicist *Lamé* (1795-1870) the *Lamé parameters*  $\lambda$  and  $\mu$ . The latter is identical with the *shear* module.  $\lambda$  does not have a straightforward physical explanation but it can be expressed in terms of the above mentioned elastic modules and Poisson's ratio, namely

$$\lambda = \kappa - 2\mu/3 = \frac{\sigma E}{(1 + \sigma)(1 - 2\sigma)} \quad (2.2a)$$

while for the shear module holds

$$\mu = \frac{E}{2(1 + \sigma)} \quad (2.2b)$$

Accordingly, the other elastic parameters can be expressed as functions of  $\mu$ ,  $\lambda$  and/or  $\kappa$ :

$$E = \frac{(3\lambda + 2\mu)\mu}{(\lambda + \mu)} \quad (2.3)$$

and

$$\sigma = \frac{\lambda}{2(\lambda + \mu)} = \frac{3\kappa - 2\mu}{2(3\kappa + \mu)} \quad (2.4)$$

For a *Poisson solid*  $\lambda = \mu$  and thus, according to (2.4),  $\sigma = 0.25$ . Most crustal rocks have a Poisson's ratio between about 0.2 and 0.3. But  $\sigma$  may reach values of almost 0.5, e.g., for unconsolidated, water-saturated sediments, and even negative values of  $\sigma$  are possible for synthetic materials (see Tab. 2.1 in section 2.2.3).

The elastic parameters govern the velocity with which seismic waves propagate. The *equation of motion* for a continuum can be written as

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \partial_j \tau_{ij} + \mathbf{f}_i, \quad (2.5)$$

with  $\rho$  - density of the material,  $u_i$  - displacement,  $\tau_{ij}$  - stress tensor and  $\mathbf{f}_i$  - the body force term that generally consists of a *gravity term* and a *source term*. The gravity term is important at low frequencies in *normal mode seismology* (see 2.4), but it can be neglected for calculations of body- and surface-wave propagation at typically observed wavelengths. Solutions of Eq. (2.5) which predict the ground motion at locations some distance away from the source are called *synthetic seismograms* (see Figs. 2.79, 2.80 and 2.82).

In the case of an inhomogeneous medium, which involves gradients in the Lamé parameters, Eq. (2.5) takes a rather complicated form that is difficult to solve efficiently. Moreover, in the case of strong inhomogeneities, transverse and longitudinal waves (see below) are not decoupled. This results in complicated particle motions. Therefore, most methods for synthetic seismogram computations ignore gradient terms of  $\lambda$  and  $\mu$  in the equation of motion by modeling the material either as a series of homogeneous layers (which also allows to approximate gradient zones; see *reflectivity method* by Fuchs and Müller, 1971; Kennett,

1983; Müller, 1985) or by assuming that variations in the Lamé parameters are negligible over a wavelength  $\Lambda$  and thus these terms tend to zero at high frequencies (*ray theoretical* approach; e.g., Červený et al., 1977; Červený, 2001; Chapman, 2002). In homogeneous media and for small deformations, however, the *equation of motion* for seismic waves outside the source region (i.e., without the source term  $\mathbf{f}_s$  and neglecting the gravity term  $\mathbf{f}_g$ ) takes the following simple form:

$$\rho \ddot{\mathbf{u}} = (\lambda + 2\mu)\nabla\nabla\cdot\mathbf{u} - \mu\nabla\times\nabla\times\mathbf{u} \quad (2.6)$$

with  $\mathbf{u}$ -displacement vector and  $\ddot{\mathbf{u}}$ , its second time derivative, the acceleration vector.

The first term on the right side of Eq. (2.6) contains the divergence of vector  $\mathbf{u}$  which is the scalar product  $\text{div } \mathbf{u} = \nabla \cdot \mathbf{u}$  of  $\mathbf{u}$  with the Nabla vector operator

$$\nabla = (\partial/\partial x)\mathbf{i} + (\partial/\partial y)\mathbf{j} + (\partial/\partial z)\mathbf{k}$$

and  $\mathbf{i}$ ,  $\mathbf{j}$ , and  $\mathbf{k}$  the components of the unity vector. and describes a volume change (compression and dilatation) which always contains some (rotation free) shearing too, unless the medium is compressed hydrostatically (as in Fig. 2.2 top)..

Further holds:  $\nabla \nabla = \nabla^2 = \Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ .

In contrast, the second term on the right side of (2.6) is a vector product of the Nabla operator with a rotation or curl of  $\mathbf{u}$ .  $\text{rot } \mathbf{u} = \nabla \times \mathbf{u}$ , with the vector components

$$\begin{aligned} \text{rot } u_x &= \partial u_z/\partial y - \partial u_y/\partial z \\ \text{rot } u_y &= \partial u_x/\partial z - \partial u_z/\partial x \\ \text{rot } u_z &= \partial u_y/\partial x - \partial u_x/\partial y \end{aligned}$$

describes a change of shape without volume change (pure shearing).

Eq. (2.6) provides the basis for most body-wave synthetic seismogram calculations. Although it describes rather well most basic features in a seismic record we have to be aware that it is an approximation only for an isotropic homogeneous linearly elastic medium.

### 2.2.3 P- and S-wave velocities, waveforms and polarization

Generally, every vector field, such as the displacement field  $\mathbf{u}$ , can be decomposed into a rotation-free ( $\mathbf{u}^r$ ) and a divergence-free ( $\mathbf{u}^d$ ) part, i.e., we can write  $\mathbf{u} = \mathbf{u}^r + \mathbf{u}^d$ . Since the divergence of a curl and the rotation of a divergence are zero, we get accordingly two independent solutions for Eq. (2.6) when forming its scalar product  $\nabla\cdot\mathbf{u}$  and vector product  $\nabla\times\mathbf{u}$ , respectively:

$$\frac{\partial^2(\nabla\cdot\mathbf{u})}{\partial^2 t} = \frac{\lambda + 2\mu}{\rho} \nabla^2(\nabla\cdot\mathbf{u}^r) \quad (2.7)$$

and

$$\frac{\partial^2 (\nabla \times \mathbf{u})}{\partial^2 t} = \frac{\mu}{\rho} \nabla^2 (\nabla \times \mathbf{u}^d). \quad (2.8)$$

Eqs. (2.7) and (2.8) are solutions of the wave equation for the propagation of two independent types of seismic *body waves*, namely *longitudinal (compressional - dilatational)* P waves and *transverse (shear)* S waves. Their velocities are

$$v_p = \sqrt{\frac{\lambda + 2\mu}{\rho}} = \sqrt{\frac{\kappa + 4\mu/3}{\rho}} \quad (2.9)$$

and

$$v_s = \sqrt{\frac{\mu}{\rho}}. \quad (2.10)$$

Accordingly, for a Poisson solid with  $\lambda = \mu$   $v_p/v_s = \sqrt{3}$ . This comes close to the  $v_p/v_s$  ratio of consolidated sedimentary and igneous rocks in the Earth's crust (see Tab. 2.1). Eqs. (2.9) and (2.10) also mean that P (*primary*) waves travel significantly faster than S (*secondary*) waves and thus arrive ahead of S in seismic records (see Fig. 2.4).

Values of  $\mu$  and  $\kappa$  vary significantly depending on the highly variable composition, density (degree of compaction) and fabric of rock material both in the upper crust and in a rather systematic manner with depth in the deeper Earth interior. There, these parameters are largely pressure and temperature controlled. Accordingly, values for  $v_p$  range between an approximate average of 5.8 km/s in the upper crust and 13.7 km in the lowermost mantle and for  $v_s$  between 0 km/s in the liquid outer core, about 3.4 for the upper crust and 7.3 km/s in the lowermost mantle. For details as a function of depth see the 1-D Earth models in DS 2.1 and Figure 2.76 in section 2.7.1 of this Chapter. Of interest may be, although seismologically irrelevant, that diamonds have the highest P-wave velocity of 18.0 km/s of all natural materials.

For near surface materials, ranging from water over muddy or unconsolidated clastic rocks via porous consolidated to almost pore-free outcropping ultramafic hard rocks, the range of  $v_p$  and  $v_s$  variations is comparably large yet with significantly smaller absolute values of  $v_p$  and  $v_s$  than for crustal averages (see Tab. 2.1 and Fig. 2.3). According to Eqs. (2.5), (2.9) and (2.10) the Poisson's ratio  $\sigma$  depends on  $v_p$  and  $v_s$ . When knowing the ratio  $v_p/v_s$ ,  $\sigma$  can be derived from the relationship

$$\sigma = (v_p^2/v_s^2 - 2) / 2(v_p^2/v_s^2 - 1) \quad (2.11)$$

or, when knowing the Poisson's ratio of rock material, the related  $v_p/v_s$  can be inferred. Tab. 2.1 gives approximate average values for  $\sigma$  for some Earth, natural and synthetic materials. Where available, they have been complemented by the related elastic modules  $\kappa$  and  $\mu$ , the density  $\rho$  and/or the seismic velocities  $v_p$  and  $v_s$ . Additionally, Fig. 2.3 presents some of the pioneering early results by Pickett (1963) which reveal distinct differences of the ratio  $v_p/v_s$  for limestone, dolomite and clean sandstone, thus demonstrating the usefulness of  $v_p/v_s$  as a lithological indicator. For shallow seismic surveys in conjunction with engineering seismological and microzonation/site effect investigations this may be of great help.

**Tab. 2.1** Values (averages and/or approximate ranges) of elastic constants, density, Poisson's ratio and seismic wave velocities for some selected materials, unconsolidated sediments, sedimentary rocks of different geologic age and igneous/plutonic rocks. Values for granite relate to 200 MPa confining pressure, corresponding to about 8 km depth, for basalt to 600 MPa (about 20 km depth), and for Peridotite, Dunite and Pyroxenite to 1000 MPa (about 30 km depth) (compiled from Hellwege, 1982; Castagna et al., 1985; Lillie, 1999; and Wikipedia). Ranges are given in brackets.

**Fig. 2.3** Relationship between  $v_p$  and  $v_s$  of limestone, dolomite, and sandstone according to data published by Pickett (1993), rescaled to SI units and velocity instead of slowness. Note the non-linearity in the velocity scales due to the rescaling.

Comments and conclusions drawn from Tab. 2.1 and Fig. 2.5 are:

- The Poisson's ratio varies for isotropic materials between 0 and 0.5;
- If  $\sigma = 0.5$  then the volume of an elastic body remains constant under deformation;
- If  $\sigma < 0.5$  then the volume increases under tensional load and shrinks under pressure;
- If  $\sigma > 0.5$  then the volume shrinks under tensional load. This may be the case, e.g., for some porous materials such as polymer foams or carbon fiber compounds depending on the fiber orientation;
- Negative values of  $\sigma$  are possible only in some rare synthetic materials, resulting, in the case of length stretching (as in Fig. 2.2 below) in a cross-extension instead of a length extension (so-called auxetic behavior) ;
- For the same material, shear waves travel always slower than compressional waves;
- The higher the rigidity of the material, the higher the P- and S-wave velocities;
- The rigidity usually increases with density  $\rho$ , but more rapidly than  $\rho$ . This explains why denser rocks have normally faster wave propagation velocities although  $v^2 \sim 1/\rho$  ;
- Fluids (liquids or gasses) have no shear strength ( $\mu = 0$ ) and thus do not propagate shear waves;
- For the same material, compressional waves travel slower through its liquid state than through its solid state (e.g., water and ice, or, in the Earth's core, through the liquid outer and solid inner iron core, respectively).

More specifically, Castagna et al. (1985) documented for clastic silicate rocks a very large range of velocity variations depending on composition, grain size, porosity, fluid saturation etc. E.g.,  $v_p$  and  $v_s$  vary for geopressed shaly rocks between 3.0-5.2 km/s and 1.5-3.5 km/s and for dry sand and sandstones, depending on the degree of compaction, cementation

material, porosity and fluid saturation in an even wider range ( $v_p = 0.3 - 5.5$  km/s and  $v_s = 0.2 - 3.5$  km/s). When normalizing bulk and shear module to density and comparing dry and liquid saturated porous rocks for equal bulk module then the shear module of dry rock is significantly higher than for water saturated rocks, whereas for equal P-wave velocity the bulk module of dry rock is usually significantly lower than for saturated rock. The latter is an important indicator in exploration seismology for saturated reservoir rocks. For more details we refer to the most recent textbook on physical properties of rocks by Schön (2011).

Fig. 2.4 shows a record of a local earthquake which clearly shows the first arriving P and the later arriving S onset (with larger amplitudes and longer periods).

**Fig. 2.4** The three components of ground-velocity proportional digital records of the P and S waves from a local event, an aftershock of the Killari-Latur earthquake, India (18.10.1993), at a hypocenter distance of about 5.3 km.

Note the simple *transient waveform* (*wavelet*) of P in the Z-component of Fig. 2.3. The waveform and duration of the primary body wave is related to the shape and duration of the source-time function. It is for an earthquake shear rupture usually a more or less complex displacement step (Fig. 2.5) which can be described by the moment-release function  $M(t)$ . In the *far-field*, i.e., at distances larger than the source dimension and several wavelengths of the considered signal, the related displacement  $u(t)$  looks, in the idealized case, bell-shaped and identical with the moment-rate  $\dot{M}(t)$  (or velocity source-time) function (Fig. 2.5 middle). The far-field pulse shape is given by eq. (10.13) in Aki and Richards (2002), provided fault length  $L$ , wavelength  $\lambda$  and source-receiver distance  $r_0$  satisfy the constraint  $L^2 \ll 0.5 \lambda r_0$ . The base-width of this *far-field displacement source pulse*  $u(t)$  corresponds to the duration of displacement at the source (see moment rate source-time functions in Fig. 3.9 of Chapter 3). However, usually modern broadband seismometers record ground velocity  $\dot{u}(t)$  instead of ground displacement. The recorded waveform then looks similar to the ones seen in Fig. 2.4 and Fig. 2.5 bottom. The period of the wavelet  $\dot{u}(t)$  then corresponds to the duration of the displacement of the source,  $\tau_s$ .

This waveform of primary body waves will be slightly changed due to frequency-dependent attenuation and other wave-propagation effects, e.g., those that cause phase shifts (see section 2.5.4.3). But the duration of the body-wave ground-motion wavelet (or wave-group) will remain essentially that of the source process, independent of the observational distance, unless

it is significantly prolonged and distorted by the coda of scattered waves (e.g., Figs. 2.42 and 2.43) and/or by narrowband seismic recordings (see Chapter 4.2). We have made this point in order to better appreciate one of the principal differences in the appearance in seismic records of transient non-dispersed body waves on the one hand and of dispersed surface waves (see 2.3 and Figs. 2.12 and 2.13) on the other hand.

**Fig. 2.5** Relationship between near-field displacement, far-field displacement and velocity from isotropic or double-couple source earthquake shear sources (modified from Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

Fig. 2.6 depicts (exaggerated) the kind of displacements occurring from harmonic plane P and S waves. One clearly recognizes that P waves involve both a volume change and shearing (change in shape) while S-wave propagation is pure shear with no volume change. The P-wave particle motion is back and forth in the radial (R) direction of wave propagation (*longitudinal polarization*) but that of the S wave is perpendicular (*transverse*) to it, in the given case oscillating up and down in the vertical plane (SV-wave). However, S waves may also oscillate purely in the horizontal plane (SH waves) or at any angle between vertical and horizontal, depending on the source mechanism (Chapter 3), the wave propagation history, and the incidence angle  $i_0$  at the seismic station (see Fig. 2.27).

The wavelength  $\Lambda$  is defined by the distance (in km) between neighboring wave peaks or troughs or volumes of maximum compression or dilatation (see Fig. 2.6). The wave period  $T$  is the duration of one oscillation (in s) and the frequency  $f$  is the number of oscillations per second (unit [Hz] = [s<sup>-1</sup>]). The wavelength is the product of wave velocity  $v$  and period  $T$  while the wavenumber is the ratio  $2\pi/\Lambda$ . Tab. 2.2 summarizes all these various *harmonic wave parameters* and their mutual relationship.

**Fig. 2.6** Displacement patterns of a harmonic plane P wave (top) and SV wave (bottom) propagating in a homogeneous isotropic medium.  $\Lambda$  is the wavelength and  $2A$  means double amplitude. The white surface on the right is a segment of the propagating plane wavefront where all particles undergo the same motion at a given instant in time, i.e., they oscillate *in phase*. The arrows indicate the seismic rays, defined as the *normal* to the wavefront, which points in the direction of propagation (modified according to Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

**Tab. 2.2** Harmonic wave parameters and their mutual relationship.

| Name              | Symbol    | Relationships                                |
|-------------------|-----------|----------------------------------------------|
| Period            | $T$       | $T = 1/f = 2\pi/\omega = \Lambda/v$          |
| Frequency         | $f$       | $f = 1/T = \omega/2\pi = v/\Lambda$          |
| Angular frequency | $\omega$  | $\omega = 2\pi f = 2\pi/T = v \cdot k$       |
| Velocity          | $v$       | $v = \Lambda/T = f \cdot \Lambda = \omega/k$ |
| Wavelength        | $\Lambda$ | $\Lambda = v/f = v \cdot T = 2\pi/k$         |
| Wavenumber        | $k$       | $k = \omega/v = 2\pi/\Lambda = 2\pi f/v$     |

In any case, the polarization of both P and S waves, when propagating in a homogenous and isotropic medium, is linear. This is confirmed rather well by particle motion analysis of real seismic recordings, if they are broadband (or long period). But higher frequencies, which are more strongly affected by local inhomogeneities in the Earth, show a more elliptical or irregular particle motion. Fig. 2.7 shows an example. While the rectilinearity of P is almost 1 (0.95) in the BB record it is significantly less (0.82 as an average over 5 oscillations and down to 0.68 for some single oscillations) for the short-period filtered record.

**Fig. 2.7** 3-component records at station MOX (top traces) and related plots of particle motion in the horizontal (N-E) plane and two vertical planes (Z-N and Z-E, respectively) of the P-wave onset from a local seismic event (mining collapse) in Germany (13.03.1989;  $M_l = 5.5$ ; epicenter distance  $D = 112$  km, backazimuth  $BAZ = 273^\circ$ ). Upper part: broadband recording (0.1-5 Hz); lower part: filtered short-period recording (1- 5 Hz). **Note:** The incidence angle is  $59.5^\circ$  for the long-period P-wave oscillation and  $47.3^\circ$  for the high-frequency P-wave group.

S waves are also linearly polarized when propagating in homogeneous isotropic medium. However, in the presence of anisotropy, they split into a fast and slow component. These split waves propagate with different velocity that causes some time delay and related phase shift.

Accordingly, the two split S-wave components superimpose to an elliptical polarization (Fig. 2.8). The orientation of the main axis and the degree of ellipticity are controlled by the fast and slow velocity directions of the medium with respect to the direction of wave propagation and the degree of anisotropy. Therefore, shear-wave splitting is often used to study S-wave velocity anisotropy in the Earth (e.g., Vinnik et al., 1989a and b; Silver and Chan, 1991; Bormann et al., 1993).

**Fig. 2.8** Examples of SKS and SKKS recordings and plots of particle motion at three stations of the German Regional Seismograph Network. The horizontal radial (R) and transverse (T) components are shown. They were derived by rotation of the N-S and E-W horizontal components with the backazimuth angle. The T component at BFO has the same scale as the R component, while T is magnified two-fold relative to R at BRG and MOX. The top panels show the polarization in the R-T plane. Anisotropy is manifested in all three cases by the elliptical polarization. Linear polarization is obtained by correcting the R-T seismograms for the anisotropy effect using an anisotropy model where the direction of the fast shear wave is sub-horizontal and given by the angle  $\Phi$  measured clockwise from north, and the delay time (in seconds) between the slow and the fast shear wave is given by  $\delta t$  (courtesy of G. Bock †).

## 2.3 Surface waves (P. Bormann)

### 2.3.1 Origin

So far we have considered only body-wave solutions of the seismic wave equation. They exist in the elastic full space. However, in the presence of a free surface, as in the case of the Earth, other solutions are possible. They are called *surface waves*. There exist two types of surface waves, *Love waves* and *Rayleigh waves*. While Rayleigh (LR or R) waves exist at any free surface, Love (LQ or G) waves require some kind of a near surface *wave guide* formed by a velocity increase with depth (gradient- or layer-wise). Both conditions are fulfilled in the real Earth.

SH waves are totally reflected at the free surface. Love waves are formed through constructive interference of repeated reflections of teleseismic SH at the free-surface (i.e., S3, S4, S5, etc.; see Figs. 2.58 and 2.59). They can also result from constructive interference

between SH waves, which are *post-critically reflected* (see 2.5.3.5) within a homogeneous layer (or a set of  $i$  layers with increasing  $v_{si}$ ) overlaying a half-space of higher velocity. The latter is the case of crustal layers, overlaying the upper mantle with a significant velocity increase at the base of the crust, called the “Mohorovičić-discontinuity” or *Moho* for short. The Moho marks the transition between the usually more mafic (often termed “basaltic”) lower crust and the peridotitic uppermost mantle (for related velocities see Tab. 2.1) and may, together with other pronounced intra-crustal velocity discontinuities give rise to the formation of complex guided crustal waves (see 2.3.3).

Generally, destructive interference of the upgoing and downgoing reflected SH waves will occur, except at certain discrete frequencies  $\omega$  and  $n$  multiples of it (with  $n$  as an integer). The values of  $\omega$  given for  $n = 0$  are termed the *fundamental modes* while larger values of  $n$  define the *higher modes* or *overtones*. Fig. 2.9 (top) shows the horizontal (SH type) of displacement and linear polarization of the fundamental Love-wave mode as well as the exponential decay of its amplitudes with depth.

When an SV (or P) wave arrives at the surface the reflected wave energy contains (because of *mode conversion*, see 2.5.3.4) both P and SV waves. Lord Rayleigh (1887) showed that a solution of the *wave equation* exists for two coupled *inhomogeneous* P and SV waves that propagate along the surface of a half-space. Physically, inhomogeneous waves are characterized by a *phase velocity* which is slower than the underlying body-wave speed and by amplitudes that grow or decay exponentially in directions of constant phase. P waves become inhomogeneous wave if the depth component of their *slowness*  $s$  is imaginary, i.e., when their *wave parameter*  $p = \sin i/v > 1/v_p$  (with  $i$  = *incidence angle*; for definition of terms and related formulas see section 2.5.2.1). Similarly, S waves form an inhomogeneous wave, when  $p > 1/v_s$ . Then the angle  $i$  is no longer real and it is no longer clear what the incidence angle of the wave is. Example: If for the upper crust  $v_p = 5$  km/s and  $v_s = 3$  km/s, then at an incidence angle of  $36.9^\circ$  for an SV wave at the Earth surface part of its energy is converted into a P wave which travels parallel to the surface. i.e., at an “incidence angle” of  $90^\circ$ . With further increase of  $i_{SV}$  and thus of the slowness  $p_{SV}$  the angle  $i_p$  can not grow further, it becomes imaginary and the physical displacement shows a phase shift of amount  $\phi$ , where  $\phi = \text{phase}(SP)$  for the horizontal component and  $\phi = \text{phase}(SP) + \pi/2$  for the vertical component, resulting in inhomogeneous wave with a retrograde elliptical particle motion. And further, if at the free surface of a half-space the condition  $1/v_p < 1/v_s < p$  holds then both P and SV waves become inhomogeneous. The coupled pair of these two inhomogeneous waves forms the Rayleigh waves.

While Rayleigh waves show no dispersion in a homogeneous half-space (with constant  $v_p$  and  $v_s$ ), they are always dispersed in media with layering and/or velocity gradients such as in the real Earth. Rayleigh waves travel - for a Poisson solid - with a phase velocity  $c = \sqrt{2 - 2/\sqrt{3}} v_s \approx 0.92 v_s$ , i.e., slightly slower than Love waves and thus have a larger slowness, which satisfies the condition  $1/v_p < 1/v_s < p$ . However, the exact value of  $c$  depends on  $v_p$  and  $v_s$  and is presented analytically by Malischewsky (2004).

Since Rayleigh waves originate from coupled inhomogeneous P and SV waves they are polarized in the vertical (SV) plane of propagation and due to the phase shift between P and SV the sense of their *particle motion* at the surface is *elliptical* and *retrograde* (counter clockwise). However, below a certain depth, which depends on frequency, the particle motion

is dominated by the SV component and becomes prograde elliptical (see Fig. 2.14 in the next section). Fig. 2.9 (bottom) shows schematically the displacement patterns of fundamental mode of Rayleigh waves with amplitudes decaying exponentially with depth. The short-period fundamental mode of Rayleigh type in continental areas is termed Rg.

**Fig. 2.9** Displacement patterns caused by horizontally propagating fundamental Love (top) and Rayleigh waves (bottom). In both cases the wave amplitudes decay exponentially with depth (from Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

### 2.3.2 Dispersion and polarization

The *penetration depth* below the surface increases with  $\Lambda$ . This is comparable with the frequency-dependent *skin effect* of electromagnetic waves propagating in a conducting medium with a free surface. Since the types of rocks, their rigidity and bulk module change (usually increase) with depth, the velocities of surface waves change accordingly since the longer waves “sense” deeper parts of the Earth. This results in a frequency dependence of their horizontal propagation velocity, called *dispersion*. Accordingly, while body-wave arrivals with no or negligibly small dispersion only (due to intrinsic attenuation) appear in seismic records as rather impulsive onsets or short transient wavelets (with the shape and duration depending on the bandwidth of the seismograph; see Chapter 4.2 “?”), the dispersion of surface waves forms long oscillating wave trains. Their duration increases with distance.

Usually, the more long-period surface waves arrive first (normal dispersion). But in some regions of the Earth low-velocity layers exist (e.g., the *asthenosphere* in the upper mantle; see the PREM model in 2.7, Fig. 2.77, in the depth range between about 80 and 220 km). This general trend may then be reversed for parts of the surface wave spectrum. Presentations of the propagation velocity of surface waves as a function of the period  $T$  or the frequency  $f$  are called *dispersion curves*. They differ for Love and Rayleigh waves and also depend on the velocity-depth structure of the Earth along the considered segment of the travel path (Fig. 2.10). Thus, from the inversion of surface wave dispersion data, information on the shear-wave velocity structure of the crust, and, when using periods up to about 500 s (mantle surface waves), even of the upper mantle and the transition zone to the lower mantle can be derived.

**Fig. 2.10** Group-velocity dispersion curves as a function of period for Love and Rayleigh waves (fundamental modes and overtones) (from Bullen and Bolt, *An Introduction to the Theory of Seismology*, 1985; with permission from Cambridge University Press).

The large differences in crustal thickness, composition and velocities between oceanic and continental areas (Fig. 2.11) result in significant differences between their related average group-velocity dispersion curves (Fig. 2.10). They are particularly pronounced for Rayleigh waves. While the velocities for continental Rayleigh waves vary in the period range from about 15 and 30 s only from 2.9 to 3.3 km/s, they vary much more in oceanic areas (from about 1.5 to 4.0 km/s within the same period range). Consequently, LR wave trains from travel paths over continental areas are shorter and look more clearly dispersed because the various periods follow each other at shorter time differences.

Fig. 2.12 presents an earthquake record at a *backazimuth* of  $BAZ = 85^\circ$ . This results in a rather good separation of the Rayleigh (LR) wave, recorded best in the E-W and Z component, and the Love wave (LQ), with largest amplitudes in the N-S component. Clearly recognizable are the large amplitude *Airy phases* for both waves with periods around 15 s. They are due to the group velocity minimum for continental travel paths (see Fig. 2.10). The preceding more long-period waves begin with periods around 50 s for LR and 90 s for LQ. These are already surface waves with a penetration depth into the upper mantle. The pronounced “normal” dispersion that follows is due to the slowly decreasing group velocities for both LQ and LR for periods  $T < 60$  s (LR), respectively  $T < 100$  s (LQ) until they reach their minima at periods around 15 s.

**Fig. 2.11** Cross-section through the crust along 40° northern latitude. Note the different signatures for the upper (granitic), intermediate (dioritic) and lower (mafic) continental crust and the basaltic oceanic crust. The crustal base is termed “Moho” (according to its discoverer, the Croatian seismologist Andrija Mohorovičić). The P-wave velocity increases at the Moho from about 6.5-6.8 km/s to 7.8-8.2 km/s. The continental crust is about 25 to 45 km thick (average about 35 km) and has “roots” under young high mountain ranges which may reach down to nearly 70 km. The oceanic crust is rather thin (about 8 to 12 km) with a negligible upper crust (courtesy of Mooney and Detweiler, 2002).

**Fig. 2.12** Three-component long-period seismogram (WWSSN-LP simulation filter) recorded from a shallow earthquake at the Afghanistan-Tadjikistan border region (30 May 1998,  $M_s = 6.9$ ) at station MOX ( $D = 43.2^\circ$ ,  $BAZ = 85^\circ$ ). Note that the displacement magnification of the WWSSN-LP at  $T = 50$  s and 90 s is already 3 times, respectively 9 times reduced as compared to the magnification at 15 s period (see Figure 1 in IS 3.3).

In contrast, LR wave trains with dominantly oceanic travel paths are much longer with almost monochromatic oscillations with periods between some 15 to 25 s over many minutes (Fig. 2.13), which is related to the steeply increasing group velocity branch for oceanic LR waves in this period range with velocities increasing from about 1.2 km/s to 3.8 km/s. Actually, the discovery of different surface-wave velocities along continental and oceanic paths were in the 1920s the first indication of the principle structural difference between oceanic and continental crust.

**Fig. 2.13** Record of Rayleigh waves in the long-period vertical component at the station Toledo, Spain, from an earthquake in the Dominican Republic ( $D = 6,622$  km; travel-path through the Atlantic Ocean) The largest amplitudes have a period of 25 s shortly after the LR onset and later, towards the end of the reproduced trace, a period of 16 s (copied cut-out from p. 35 of G. Payo, 1986).

Strictly speaking, when dealing with dispersive waves, one has to discriminate between the *group velocity*  $U(T)$ , with which the energy of the wave group moves and the *phase velocity*  $c(T)$ , with which the wave peaks and troughs at a given frequency travel along the surface. As seen from Fig. 2.14,  $c(T)$  is always increasing with period and larger than  $U(T)$ . When comparing Figs. 2.11 and 2.14 the significant differences between dispersion curves calculated for a global 1-D Earth model like PREM (see 2.7, Fig. 2.79 and DS 2.1) and averaged measured curves for different types of crust or mantle models become obvious.

**Fig. 2.14** Fundamental mode Love- and Rayleigh-wave dispersion curves computed for the PREM model with anisotropy (courtesy of Gabi Laske).

As shown in Fig. 2.15, the particle motion of the fundamental Rayleigh-wave mode on the surface of a uniform half space is *retrograde* and the vertical component about 1.5 times larger than the horizontal one. The horizontal component will vanish at a depth of about  $\Lambda/5$  and thus the particle motion becomes vertical linear. At larger depth the particle trajectories will be elliptical again, but because of a now dominant SV component with a *prograde* (clockwise) sense of motion. The amplitudes decay rapidly with depth. At a depth of  $\Lambda/2$ , the horizontal particle motion is about 10% of that at the surface while the vertical particle motion at the surface is reduced to about 30%.

**Fig. 2.15** Particle motion for the fundamental Rayleigh mode in a uniform half-space. Shown is one horizontal wavelength. Note the change from retrograde to prograde sense of elliptical particle motion at a depth larger about  $\Lambda/5$ . The wave propagates from left to right. The dots show the position of the same particle at a fixed distance with time increasing from the right to the left (modified from Shearer, Introduction into Seismology, 1999; with permission from Cambridge University Press).

Fig. 2.16 shows, for the event in Fig. 2.7, the 3-component broadband record of the Rayleigh-wave group and the related particle motion trajectories in three perpendicular planes. There exists indeed a strikingly clear retrograde elliptical motion in the vertical-east (Z-E) plane, as predicted by theory, which is in this case almost identical with the vertical plane of wave propagation (BAZ =  $273^\circ$ ). Also the vertical component amplitude is somewhat larger than the horizontal one, as theoretically expected too. In the horizontal plane (N-E), however, there is also some transverse energy present in this wave group. It is due to some SH energy present in the N-S component. Generally, one should be aware that the theoretically expected complete separation of LQ and LR waves in a homogeneous isotropic (horizontally layered) half-space is not absolutely true in the real Earth because of heterogeneity and anisotropy. This may cause the coupling of some Rayleigh-wave energy into Love waves and vice versa (see e.g., Malischewsky, 1987, and Meier et al., 1997), similar to S-wave splitting in the presence of anisotropy (see Fig. 2.8).

**Fig. 2.16** 3-component broadband records (top traces) and related plots of particle motion in the horizontal (N-E) plane and two vertical planes (Z-N and Z-E, respectively) of the surface-wave group of the same event as in Fig. 2.6 ( $D = 112$  km; backazimuth BAZ =  $273^\circ$ ).

It should be noted, however, that even a simple model “layer over half-space” may produce prograde particle motion for Rayleigh waves on the model surface (Malischewsky et al., 2006 and 2008). This phenomenon strongly depends on the S-wave velocity contrast, the Poisson ratio  $\sigma_1$  in the layer and the frequency. This phenomenon disappears for Poisson ratios less than 0.2 and S-wave contrasts  $v_{s1}/v_{s2}$  higher than 0.45 with  $v_{s1}$  the S-velocity in the layer and  $v_{s2}$  the S-velocity of the half-space. The frequency range is inversely proportional to the layer thickness. This has been demonstrated by way of example for the Dead Sea transform fault region in Israel. For the simplified Kiryat Shmona test site model (see Malischewsky et al., 2008)  $v_{s1}/v_{s2}$  is 0.25 and  $\sigma_1 = 0.46$  and one observes prograde motion between 11.3 Hz and 22.5 Hz for a layer thickness of 10 m and between 2.8 Hz and 5.6 Hz for a layer thickness of 40 m.

Because of the strong decay of surface wave amplitudes with depth, earthquakes deeper than the recorded wavelengths will produce significantly reduced or no surface waves. The amplitude ratio between body and surface waves in broadband records is thus a reliable quick discriminator between shallow and deep earthquakes. For shallow teleseismic earthquakes the surface wave group has generally by far the largest amplitudes in broadband and long-period records (see Fig. 2.25). This is because of their 2-D propagation along the surface of the Earth and energy decay  $\sim 1/r$  as compared to the 3-D propagation of body-waves and energy decay  $\sim 1/r^2$ . Also, the local maxima and minima in the group-velocity curves (Figs. 2.10 and 2.14) imply that surface wave energy in a wider period range around these extremes will travel with nearly the same velocity and arrive at a seismic station at about the same time, thus superimposing to large amplitudes. These amplitude maxima in the dispersive surface wave train are called *Airy phases*. For continental travel paths a pronounced Rayleigh wave Airy

phase with periods around 15 s occurs which is rather stable. For oceanic travel paths the displacement amplitude maxima are due to the Airy phase periods associated with the group velocity maximum in Fig. 2.10 between about 25 s and 60 s. However, since in classical long-period records with WWSSN-LP response the maximum gain at periods of 15 s is already reduced, usually the period are measured around 20 s only. IASPEI standard surface-wave magnitudes are either measured on WWSSN-LP response records in the period range between 18 and 22 s (Ms\_20) or on velocity broadband records in a much wider period range between 3 s and 60 s (Ms\_BB; see IS 3.3 and IASPEI, 2011). Long-period mantle Rayleigh waves have another Airy phase around  $T \approx 200$  s, associated with a group velocity minimum (see Figs. 2.10 and 2.14). Such long-period mantle surface waves are used for measuring the (almost) not saturating mantle magnitude  $M_m$  (Okal, 1992a and b; Okal and Talandier, 1989), Chapter 3).

Higher mode surface waves have different depth dependence than fundamental modes and sample deeper structure than that probed by fundamental modes of the same period (see section 2.3.4 on mantle surface waves).

### 2.3.3 Crustal surface waves and guided waves

Because of the broad maximum of the group velocity of Love-wave continental overtones with periods between about 3 and 10 s and group velocities around 3.5 km/s they may appear in seismic records as an onset-like Lg-wave group with almost no dispersion, sometimes even in pairs (Lg1, Lg2) because of the nearby local minimum in the dispersion curve around 2 s (see Fig. 2.11). Since the group velocity of Lg-waves is higher than that of continental fundamental modes with  $T < 30$  s, they may appear in broadband records with an upper corner period around 20 s as clear forerunners to the surface wave group. The Lg-wave group, however, is not a pure continental Love wave but rather a complex *guided crustal* wave. It is caused by superposition of multiple S-wave reverberations between the surface and the Moho and SV to P and/or P to SV conversions as well as by scattering of these waves at lateral heterogeneities in the crust (for definition of phase nomenclature see IS 2.1 as well as Storchak et al. 2003 and 2011). Accordingly, Lg waves are also recorded on vertical components (see Fig. 2.17). Beyond epicenter distances of about  $3^\circ$  their amplitude maximum is usually well-separated from the earlier onset of Sg. Lg usually dominates seismic records of local and regional events and may propagate rather effectively along continental paths, in shield regions in particular, over a few thousand kilometers (see Fig. 2.17).

Because of the stability of Lg amplitude-distance relationships in continental areas this phase is well suited for reliable magnitude estimates of regional events (see 3.2.6.6) and mb\_Lg has become a new IASPEI standard (see IS 3.3 and IASPEI, 2011). The propagation of Lg may be barred by lateral changes in the velocity structure such as sedimentary basins, Moho topography, the transition between oceanic and continental crust and the boundaries between different tectonic units.

**Fig. 2.17** Records of Lg, together with other crustal phases, in records of a Kola peninsula mining blast ( $M_l = 2.4$ ) at the Norwegian array stations ARCES (distance  $D = 391$  km; upper two traces) and NORES ( $D = 1309$  km, bottom traces). cb and sb – P- and S-wave beams (see Chapter 9) of the vertical elements of the array, filtered with 2-8 Hz and 1-4 Hz, respectively (courtesy of J. Schweitzer).

Near-surface seismic events such as industrial or underground nuclear explosions, rock-bursts etc. also generate short-period fundamental-mode Rayleigh waves, termed Rg. Rg waves show normal dispersion and have relatively large amplitudes on vertical components (see Fig. 2.18). They are not excited by seismic events deeper than about one wavelength and thus a good discriminator between often man-made seismic sources near the surface and most natural earthquakes with depths most likely between 5 and 25 km (crustal earthquakes) or even deeper (intermediate or deep earthquakes in subduction zones). Rg is more strongly attenuated than the guided wave Lg. Its range of propagation is limited to less than about 600 km. However, up to about 200 km distance Rg may dominate the recorded wave train from local near-surface seismic events.

**Fig. 2.18** Mining induced rock burst south of Saarbrücken, Germany, recorded at station WLF in Luxemburg ( $D = 80$  km,  $h = 1$  km,  $M_l = 3.7$ ). Note the strong dispersive Rg phase with periods between 1.2s and 2.8 s.

### 2.3.4 Mantle surface waves

Love and Rayleigh waves travel along great circle paths around the globe. Surface waves from strong earthquakes may travel several times around the Earth. They are termed *global surface waves*. The first surface wave group arriving at a seismic station at the epicenter distance  $\Delta^\circ$  will have taken the shorter great circle while the later arrival has traveled the major arc path over  $360^\circ - \Delta^\circ$  (Fig. 2.19).

**Fig. 2.19** Great circle paths for the first three arrivals of global Rayleigh waves.

These arrival groups are called R1, R2, R3, R4 etc. for Rayleigh waves and G1, G2, G3, G4 etc. for Love waves, respectively. R3 (or G3) have traveled over  $360^\circ + \Delta^\circ$  and R4 over  $720^\circ - \Delta^\circ$  etc. Fig. 2.20 gives an example for long-period records of P, SV, SH, R1, R2, G1 and G2 in the vertical (Z) and the two horizontal components rotated into the radial (wave propagation) direction R and transverse direction T. As expected, P appears only on Z and R while S has both SV and SH energy. The Love wave groups G1 and G2 are strongest in T and arrive ahead of R1 in R2, which are visible only on the R and Z components. But Fig. 2.20 is also a

good example for inverse (negative) dispersion in the mantle Rayleigh-wave groups. Their periods range in the record from about 60 s to almost 200 s, with the longest periods arriving at the end of the R1 and R2 groups. This is just the period range of inverse dispersion according to Fig. 2.11 for both continental and oceanic mantle Rayleigh waves. This inverse dispersion is not seen in records of classical long-period WWSSN -LP seismographs with a peak magnification around 15 s because the corresponding periods are filtered out by the system response with a hundred times lower gain at 200s than at 15 s.

**Fig. 2.20** Records of the March 11, 1989 Tonga trench earthquake ( $h = 235$  km) in the Z, R and T components of the IRIS/IDA station NNA in Peru ( $D = 93.7^\circ$ ) (from Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

Further, one should note in Fig. 2.20 that these surface waves originate from an earthquake in the Tonga trench subduction zone at a depth of  $h = 230$  km. This seems to contradict the above statement, that no or only weak surface waves can be observed from deep earthquakes. However, there is no contradiction. As discussed above, the depth of penetration (and thus constructive interference) of surface waves increases with their wavelength. For the periods considered in Fig. 2.20  $\Lambda$  ranges between about 230 and 880 km, i.e., it is comparable or larger than the source depth. Therefore, we still can expect significant surface wave energy in

that period range for the largest amplitudes in Fig. 2.20. However, no periods below 50 s, as recorded in classical narrow-band long-period records, are recognizable in these long-period bandpass-filtered accelerometer records. Note, however, that in such records the displacement amplitudes are suppressed proportional to  $1/T^2$ , thus not representing correctly the spectral amplitude ratios. The longest period recognizable in the radial component record of Fig. 2.20 has a period of about 200 s, corresponding to the group velocity minimum of the fundamental mantle Rayleigh wave (Airy phase). In contrast, the pronounced wave group with much shorter periods ( $T$  around 70 s), with largest amplitudes arriving some 10 min. earlier, are mantle penetrating higher modes. According to Romanovicz (2011; courtesy of Yuancheng Gung) computations based on the PREM model (Dziewonski and Anderson, 1981) show that the fundamental Rayleigh-wave mode has at  $T = 150$  s its sensitivity peak around 200 km depth whereas the first two overtones have at a period of  $T = 100$  s still significant sensitivity down to the top of the lower mantle at depths around 800 km and 1200 km, respectively.

With modern very broadband (VBB) recording systems of high dynamic range (see Chapter 5) it is possible to record such long-period global mantle surface waves up to about R7, riding on oscillations of solid Earth's tides of even longer period (more than 12 hours). Fig. 2.21 shows a striking example. The successive groups of R reveal an exponential decay of amplitudes. This allows the determination of the intrinsic frequency-dependent attenuation in the crust and mantle (see 2.5.4.2).

**Fig. 2.21** Example of a very broadband (VBB) record with high dynamic range by the STS1 seismograph operated by the Nagoya University, Japan. The seismic wave groups from a magnitude 8.2 earthquake in the Kermadec Islands (October 20, 1986) are superimposed to solid Earth's tides (modified from a pamphlet of the Japanese Global Seismology Subcommittee for the POSEIDON project).

## 2.4 Normal modes (P. Bormann)

Since the Earth is not an infinite half-space but a finite body, all wave motions must be confined too. Body waves are reflected back from the surface into the Earth, surface waves orbit along great circle paths. Thus, there will be a multitude of different seismic phases arriving at a given point on the surface. Depending on their timing and periods they will interfere with each other, either in a more destructive or more constructive manner. The latter will be the case at certain resonant frequencies only. They are termed the Earth's *normal*

*modes* and provide another alternative way of representing wave propagation. An analogy is the standing wave modes of a vibrating string fixed at both ends (Fig. 2.22). The lowest frequency is called the fundamental mode; the higher modes are the overtones. This can be treated as an eigenvalue problem: the resonant frequencies are called *eigenfrequencies*; the related displacements are termed the *eigenfunctions*.

**Fig. 2.22** The first four modes of vibration of a string between fixed endpoints (from Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

One should be aware of the following points about normal modes in observatory practice:

- Any wave motion within the Earth may be expressed as a sum of normal modes with different excitation factors;
- There exist, in analogy to P/SV (Rayleigh) and SH (Love) -wave motion, *spheroidal modes* and *toroidal modes*, respectively;
- Toroidal modes involve no radial motion and are only sensitive to the shear velocity;
- Spheroidal modes have both radial and horizontal motion. They are sensitive to both compressional and shear velocities;
- Long-period spheroidal modes are sensitive to gravity and thus provide information about the density structure of the Earth that may not be obtained in any other way;
- The ellipticity of the Earth, its rotation as well as its 3-D velocity variations will cause a splitting of the eigenfrequency spectral lines. Thus the investigation of normal mode splitting allows to constrain 3-D structures of the Earth;
- Normal modes do (besides PKPdf amplitudes) provide information about the shear-wave velocity of the *inner core*;
- The decay of mode amplitudes with time has provided important information about the attenuation properties of the Earth at very long periods;
- Normal modes provide a complete set of basis functions for the computation of synthetic seismograms for surface-wave and long-period body-wave seismology.

Therefore, the collection of high-quality broadband data that also allow retrieval of normal modes is an important function of high-tech seismological broadband observatories. This requires very stable installation conditions, for horizontal seismometers in particular, e.g., in boreholes (see 7.4.5) or deep non-producing underground mines in order to reduce near surface tilt noise caused by barometric pressure variations. The latter may also be filtered out by correlating parallel recordings of seismometers and micro-barometers (e.g., Warburton and Goodkind, 1977; Beauduin et al., 1996; see Fig. 2.23). For another very good low-noise free normal mode spectrum recorded from the disastrous N-Sumatra-Andaman earthquake on December 25, 2004 see Figure 4 in IS 5.1.

First observations of some normal modes were made in conjunction with the strongest earthquake of the 20<sup>th</sup> century (Chile, 1960). Since then, further progress in seismometry and data analysis have permitted the identification of over a thousand modes and on that basis, to significantly refine velocity, density and attenuation models of the Earth (see 2.7; PREM model).

In fact, normal mode analysis in the *spectral domain* (see Chapter 4.1) is the only practical way to examine seismic records at very long periods (> 500 s) and thus with wavelengths of 2000 and more kilometers. But normal mode studies themselves are beyond the scope of routine data analysis at seismological observatories and will not be considered in this Manual. (For further readings see Gilbert and Dziewonski, 1975; Aki and Richards, 1980 and 2002; Lapwood and Usami, 1981; Lay and Wallace, 1995; Dahlen and Tromp, 1998; Kennett, 2001; Longnonné and Clévéde, 2002).

**Fig. 2.23** Normal mode spectra excited by an  $M_s = 8.2$  earthquake in the Macquarie Island region and recorded with STS1 at the stations SSB2 in France and BFO in Germany. BFO is located in an old silver mine and has very low tilt noise. The latter is high at SSB2 (broken lines) but could be filtered out (solid lines) by correlation with micro-barometric recordings (reproduced from Beauduin et al., The Effects of the Atmospheric Pressure Changes on Seismic Signals ..., Bull. Seism. Soc. Am., Vol. 86, No. 6, Fig. 8, page 1768, 1996; © Seismological Society of America).

Fig. 2.24 shows the patterns of surface and radial motions related to some of the spheroidal and toroidal modes. Their general nomenclature is  ${}_nS_l$  and  ${}_nT_l$ .  $n$  is the number of zero crossings of amplitudes with depth while  $l$  is the number of zero (nodal) lines on the surface of the sphere. Accordingly, the fundamental spheroidal “breathing” mode of the Earth is  ${}_0S_0$  because it represents a simple expansion and contraction of the Earth. It has a period of about 20 min.  ${}_0S_2$  has the longest period ( $\approx 54$  min) and describes an oscillation between an ellipsoid of horizontal and vertical orientation, sometimes termed “rugby” mode. The toroidal mode  ${}_0T_2$  corresponds to a purely horizontal twisting motion between the northern and southern hemisphere and has a period of about 44 min. Overtones  ${}_iS$  and  ${}_iT$  with  $i = 1, 2, 3, \dots$  have one, two, three or more nodal surfaces at constant radii from the center of the Earth across which the sense of radial or twisting motions reverses. A 3-D presentation of the spherical harmonic of 6<sup>th</sup> degree and 1<sup>st</sup> order shows Fig. 2.24.

Spherical harmonic of 6<sup>th</sup> degree and 1<sup>st</sup> order, corresponding to  ${}_0S_6^1$ . The distinct corresponding multiplet spectral line with average frequency of 1.03755 mHz is clearly seen in the upper two spectral plots of Fig. 2.23 for stations SSB2 and BFO.

**Fig. 2.24 Left:** Top - Surface and radial patterns of motions of spheroidal modes; Bottom: Purely radial modes involve no nodal pattern on the surface but have nodal surfaces at depth. Toroidal modes involve purely horizontal twisting of the Earth. For explanation of mode nomenclature see text (after Bolt, 1982; from Lay and Wallace, 1995, Fig. 4.24, p. 160; with permission of Elsevier Science, USA). **Right:** Singlet figure  ${}_0S_6^1$  (courtesy of P. Malischewsky, 2012; modified version of Figure 3 in Malischewsky, 2011; calculated with Mathematica).

In summary, strong earthquakes can make the planet Earth ring like a bell. Seismologists may be compared with experienced bell-makers who are able to infer from the complex sound spectra of a bell not only its size and general shape but also the composition of the alloy of which it is made.

## 2.5 Seismic rays, travel times, amplitudes and phase shifts (P. Bormann)

### 2.5.1 Introduction

So far we have introduced seismic body and surface waves more from a physical and phenomenological point of view. We have learned why these different wave types travel with different velocities and consequently appear in the seismogram at different times. We have seen that body waves form short transient wavelets (see Figs. 2.4), in contrast to the prolonged and dispersed wave trains of surface waves (e.g., Figs. 2.12 and 2.13). Fig. 2.25 shows another seismic record of an earthquake  $73^\circ$  away. Besides the discussed primary body and surface waves (P, S, LQ, and LR), several additional arrivals are marked in the seismogram and their symbols are given. These energy pulses are mainly caused by reflection or mode conversion of primary P or S waves either at the free surface of the Earth or at velocity-density discontinuities inside the Earth.

**Fig. 2.25** Digital broadband record of the Seattle  $M_w = 6.8$  earthquake on 28 February 2001 at the station Rüdersdorf (RUE), Germany (epicenter distance  $D = 73^\circ$ ). Note the detailed interpretation of secondary phase onset (courtesy of S. Wendt).

A proper understanding of these arrivals is essential for a correct phase identification that in turn is of great importance for event location (see IS 11.1) and magnitude determination (see IS 3.3 and EX 3.1) but also for later determination of seismic velocities inside the Earth, especially also for S waves. We will introduce and use the concept of seismic rays to understand and illustrate the formation and propagation of these different wave arrivals.

Seismic ray theory is a very convenient and intuitive way to model the propagation of seismic energy and in particular of body waves. It is generally used to locate earthquakes and to determine focal mechanisms and velocity structure from body wave arrivals. Seismic ray theory is essentially analogous to optical ray theory, including phenomena like ray-bending, focusing and defocusing. We just summarize the very basics. For more detailed treatments see Červený (2001) and Chapman (2002).

Using ray theory, it is important to keep in mind that it is an approximation that does not include all aspects of wave propagation. Ray theory is based on the so-called *high-frequency approximation* which states that fractional changes in velocity gradient over one seismic wavelength are small compared to the velocity. In other words, we may use ray theory only if the dimensions of structures to be considered are larger than the seismic wavelengths used.

These conditions are valid for most parts of the Earth (see global model in Fig. 2.79) and for the wavelengths that are usually recorded and analyzed in seismological observatory practice. The problem of relatively sharp boundaries, as for example the crust-mantle interface (Moho - discontinuity), discontinuities in the upper mantle, and the core-mantle boundary (CMB) or the inner-core boundary (ICB) can be tackled by matching the boundary conditions between neighboring regions in which the ray solutions are valid. Yet, the derivation and practical application of more detailed 3D-models also for earthquake location gain nowadays strong momentum (see section 2.7.2).

## 2.5.2 Huygens's and Fermat's Principle and Snell's Law

In classical optics, *Huygens's Principle* governs the geometry of a wave surface. It states that every point on a propagating wavefront can be considered the source of a small secondary wavefront that travels outward at the wave velocity in the medium at that point. The position of the wavefront at a later time is given by the tangent surface of the expanding secondary wavefronts. Since portions of the primary wave front, which are located in relatively high-velocity material, produce secondary wavefronts that travel faster than those produced by points in relatively low-velocity material, this results in temporal changes of the shape of the wavefront when propagating in an inhomogeneous medium. Since rays are defined as the normals to the wavefront, they will change accordingly. Rays are a convenient means for tracking an expanding wavefront. Fig. 2.26 depicts the change of direction of a plane wavefront and associated rays when traveling through a discontinuity which separates two homogeneous media with different but constant wave propagation velocity.

*Fermat's Principle* governs the geometry of the ray path. It states that the energy (or ray) will follow a *minimum time path*, i.e., it takes that path  $d$  between two points, which takes an extreme travel-time  $t$  (i.e., the shortest or the longest possible travel time, with  $\partial t / \partial d = 0$ ). Such a path is called *stationary*. In case of a stationary time path there exist three possibilities, depending on the value (sign) of the higher derivatives of  $\partial t / \partial d$ :

|     |                                   |                                                                                                             |
|-----|-----------------------------------|-------------------------------------------------------------------------------------------------------------|
| for | $\partial^2 t / \partial d^2 > 0$ | the ray follows a true <i>minimum time path</i> ,                                                           |
| for | $\partial^2 t / \partial d^2 < 0$ | the ray follows a <i>maximum time path</i> and                                                              |
| for | $\partial^2 t / \partial d^2 = 0$ | i.e., in case of an inflection point of the travel-time curve, the ray follows a <i>minimax time path</i> . |

Different kinds of seismic waves follow different time paths, e.g., the reflected waves pP (see Fig. 2.62) a true minimum path, the PP or the SKKS reflection (Fig. 2.52) a minimax path and the reflected wave P'P' (PKPPKP) (Fig. 2.53) a true maximum path. Note that the character of the stationary path influences the character (phase shift) of the reflected waveform. Whenever a seismic ray travels in some parts of its ray path as a maximum time ray, it touches a *caustic*. This caustic can be a focusing point (see 2.5.3.3 or 2.5.3.4) or a surface along which seismic rays superimpose each other (see 2.5.4.3). In any case, prominent phase distortion can be observed and may have to be taken into account when analyzing seismograms, depending on the task.

### 2.5.2.1 Snell's Law for a flat Earth

From *Fermat's Principle* follows, with some simple geometry and mathematics, *Snell's Law* of wave refraction (e.g., Aki and Richards, 1980 and 2002; Lay and Wallace, 1995; Shearer, 1999; Červený, 2001; Kennett, 2001):

$$\sin i/v = s \sin i = s_x = 1/v_{\text{app}} \equiv p = \text{constant} \quad (2.12)$$

where  $i$  is the angle of incidence, measured between the ray and the vertical (see Fig. 2.26),  $v$  is the velocity (speed) of wave propagation in the medium,  $s = 1/v$  is called slowness, and  $p$  is the so-called ray parameter,  $v/\sin i = v_{\text{app}}$  is the apparent horizontal wave propagation velocity in  $x$ -direction with  $v_{\text{app}} = \infty$  for  $i = 0$  (vertical incidence of the ray) and  $s_x = 1/v_{\text{app}}$  is the horizontal component of the slowness vector  $s$ . Note, however, that  $p$  is constant for laterally homogeneous media only. In Fig. 2.26 the refraction of a seismic wavefront and of a related seismic ray across the interface of two half spaces with different but constant seismic velocities  $v_1$  and  $v_2$  is sketched. Such an instantaneous velocity jump is called first-order discontinuity. Because the ray parameter must remain constant across the interface, the ray angle has to change:

$$\sin i_1/v_1 = \sin i_2/v_2 = s_1 \sin i_1 = s_2 \sin i_2. \quad (2.13)$$

**Fig. 2.26** A plane wavefront with the associated ray crossing a medium boundary with  $v_2 > v_1$ . Because of the velocity increase in medium 2 the ray is refracted away from the vertical, i.e.,  $i_2 > i_1$ .

### 2.5.2.2 Snell's Law for the spherical Earth

Above, a flat-layered case was considered. Yet the Earth is a sphere and curvature has to be taken into account at distances greater than about  $12^\circ$ . In this case the ray parameter has to be modified. In Fig. 2.27 a ray is sketched in a sphere composed of two concentric shells 1 and 2 of different but constant velocity  $v_1$  and  $v_2$  or slowness  $s_1 = 1/v_1$  and  $s_2 = 1/v_2$ , respectively. At the first interface between medium 1 and 2, Snell's Law must be satisfied locally, i.e.,:

$$s_1 \sin i_1(r_1) = s_2 \sin i_2(r_2) \quad (2.14)$$

for  $r_1 = r_2$ . Inside shell 2, however, despite  $v_2 = \text{const.}$ , the incidence angle changes as the ray progresses, namely,  $i_1(r_1) \neq i'_2(r'_2)$ . If we project the ray in medium 2 further to its turning point where  $r = r_{\min}$  we see from the set of right triangles that the following relationship holds:

$$s_1 r_1 \sin i_1 = s_2 r'_2 \sin i'_2.$$

This is true along the entire ray path and we can generalize

$$s r \sin i = r \sin i/v \equiv p, \quad (2.15)$$

which is the modified Snell's Law for a spherical Earth.

**Fig. 2.27** Ray geometry for an Earth model consisting of two spherical shells of constant but different velocity  $v_1$  and  $v_2$ .

In fact, it has been Benndorf (1905 and 1906) who first published that in the case of a spherically symmetric Earth model apparent velocity and thus the seismic ray parameter  $p$  are constant along their whole ray path (*Benndorf's Law*).

## 2.5.3 Rays and travel times in laterally homogeneous (1-D) media

### 2.5.3.1 Velocity gradient

It is true for most parts of the Earth that the seismic velocity increases with depth due to compaction of the material. Consider a ray travelling downwards through a stack of layers with constant velocities  $v_i = 1/s_i$  each, however, increasing layer velocities with depth (Fig. 2.28). Applying Snell's law

$$p = s_1 \sin i_1 = s_2 \sin i_2 = s_3 \sin i_3 \dots \quad (2.16)$$

we can derive the incidence angle  $i$ , that is continuously increasing with depth, and finally approaching  $90^\circ$ . At  $i = 90^\circ$  the ray is at its *turning point*  $tp$ .

**Fig. 2.28** Ray through a multi-layered model with constant velocity within the layers but increasing velocity with depth of the layers. The ray angle  $i$  increases accordingly with depth.

This can be generalized by modeling a velocity gradient with depth as a stack of many thin layers with constant velocity. Rays and travel times for this case are sketched in Fig. 2.29. The plot of arrival times  $t$  versus distance  $x$  is generally called the *travel-time curve*. The tangent  $dt_i/dx_i$  on the travel-time curve at any distance  $x_i$  corresponds to the inverse of the horizontal wave propagation velocity  $1/v_{appi}$  and thus to the ray parameter  $p_i$  of that ray which comes back to the surface at  $x_i$ . Because of  $\sin i = \sin 90^\circ = 1$  at the turning point of the ray, we can determine the velocity  $v_{tp}$  at the turning point of the ray either from the gradient of the travel-time curve at  $x_i$  via  $p_i = dt_i/dx_i = 1/v_{tp}$  or by knowing the sub-surface velocity  $v_{oi}$  at station  $x_i$  and measuring the incidence angle  $i_{oi}$  at that station ( $v_{tp} = v_{oi} / \sin i_{oi}$ ).

**Fig. 2.29** Ray paths (middle) and travel-time curve (right) for a model with velocity  $v$  gradually increasing with depth  $z$  (left). The incidence angle  $i$  increases continuously until it reaches  $90^\circ$  at the turning point  $tp$ , then the rays turn up again to reach the surface at  $x_i$ . On the travel-time curve each point comes from a different ray with a different slowness and ray parameter  $p$ . The gradient of the tangent on the travel time curve at  $x_i$  is the ray parameter  $p_i = dt_i/dx_i$ . In the considered case of modest velocity increase with depth the distance  $x$  increases with decreasing  $p$ . The related travel-time curve is termed *prograde*.

### 2.5.3.2 Effect of a sharp velocity increase

Next we consider the effect of a sharp velocity increase, which may be an increase in gradient (second-order discontinuity) or an instantaneous velocity jump (first-order discontinuity). Fig.

2.30 shows on the left side a hypothetical velocity-depth model in the upper crust of the Earth together with the related seismic rays and on the right the corresponding travel-time curves in the reduced-time presentation  $t_{\text{red}} = t - (x/v_{\text{red}})$ . Travel-time usually increases with distance. Consequently, presenting absolute travel-time curves for large epicenter distances would require very long time-scale axes. Moreover, small changes in  $dt/dx$  are then not so well recognizable. Therefore, in order to reduce the time scale and to increase the resolution of changes in slowness, travel-time curves are often represented as *reduced travel-time curves*, in which  $t_{\text{red}} = t - x/v_{\text{red}}$  is plotted (for some constant  $v_{\text{red}}$ ) as a function of  $x$ . The reduction velocity  $v_{\text{red}}$  is usually chosen so as to be close to the mean velocity in the considered depth range or of the considered seismic phase. Its reduced travel-time is then constant and positive or negative slowness deviations are clearly recognizable.

In the ray diagram of Fig. 230 one recognizes that at certain distances  $x$ , rays with different incidence angles may emerge. Modest velocity gradients in the upper and lower part of the velocity profile result in rays which return to the surface with increasing distance  $x$  for decreasing ray parameter  $p$ . This produces prograde travel-time branches (yellow and green branches in the  $t_{\text{red}}-x$  plot). In contrast, a strong velocity gradient leads to decreasing  $x$  with decreasing  $p$  and thus to a receding (retrograde) travel-time branch (red). Thus, a strong gradient zone between two weak gradient zones results in a *triplication* of the travel-time curve. The endpoints of the triplication are called *caustics*. At the caustics (positions  $x_1$  and  $x_2$ ) rays, which have left the source under different take-off angles, arrive at the surface at the same time. This causes a focusing of energy, large amplitudes and a waveform distortion (see 2.5.4.3). Fig. 2.31 shows qualitatively, with the same color coding as in Fig. 2.30, the changes in the ray parameter  $p$  with distance  $x$  for the prograde and retrograde travel-time branch(es) of a triplication.

**Fig. 2.30 Left:** Velocity-depth profile in a model of the upper crust with a strong velocity gradient between about 2.5 and 6 km depth and related seismic rays from a surface source. **Right:** ray diagram and  $t_{\text{red}}-x$  relation for the given model;  $v_{\text{red}} = 4.5$  km/s. Note the differently colored segments of the velocity-depth distribution and of the travel-time branches that relate to the seismic rays given in the same color. Yellow and green: prograde travel-time curves, red: retrograde travel-time curve. Note the two lowermost blue rays that have already been affected by a low-velocity zone below 10 km depth (courtesy of P. Richards, 2002.)

**Fig. 2.31** Distance  $x$  as a function of ray parameter  $p$  for *triplications*. Note that the colors in this diagram correspond to the colors of the related rays and velocity segments in Fig. 2.30.

The gradient of the retrograde travel-time branch and the position  $x_1$  and  $x_2$  of the caustics are controlled by the thickness and the velocity-gradient in this strong-gradient zone. Similar triplications develop in the presence of first-order discontinuities with positive velocity jump. In this case the retrograde branch relates to the post critical reflections from such a discontinuity (see Fig. 2.35 in 2.5.3.6). The identification and quantification of such first- and second-order discontinuities is of greatest importance for the understanding of related changes in physical and/or compositional properties in the Earth. This necessitates, however, that not only first arrivals of seismic waves but also later, secondary arrivals are identified and their amplitudes measured. Since the latter may follow rather closely to the former, their proper identification and onset-time measurement may be difficult in very narrow-band filtered recordings because of their strong signal distortion (see figures in Chapter 4, section 4.2).

**Fig. 2.32** Triplications of the P-wave travel-time curve (here in reduced presentation) due to the 410 km and 660 km upper mantle/transition zone discontinuities, calculated according to the IASP91 velocity model (Kennett and Engdahl, 1991) (section 2.7, Fig. 2.76). The P waves diving directly below the 410 km (660 km) are called P410 (P660); the phases P410P and P660P are the over- reflections from the outer side of these discontinuities, respectively.

Two of the most pronounced velocity and density increases occur at about 410 and 660 km below the surface (section 2.7, Figs. 2.51 and 2.53). They mark the lower boundary of the upper mantle and of the transition zone from the upper mantle to the lower mantle, respectively. Both are caused by phase transitions of the mantle material into states of higher density at critical pressure-temperature (P-T) conditions. These two pronounced discontinuities result in triplications of the P-wave travel-time curves in the distance range between about  $14^\circ$  and  $28^\circ$  (Fig. 2.31) associated with a strong increase of P-wave amplitudes around  $20^\circ$  (so-called  $20^\circ$  discontinuity; see Fig. 3.34 in Chapter 3).

### 2.5.3.3 Effect of a low-velocity zone

Velocity generally increases with depth due to compaction, however, lithologic changes or the presence of water or melts may result in low-velocity zones (LVZ). Fig. 2.33 shows the effects of an LVZ on seismic rays and the travel-time curve. The latter becomes discontinuous, forming a shadow zone within which no rays emerge back to the surface. Beyond the shadow zone the travel-time curve continues with a time off-set (delay) from a caustic with two branches: one retrograde branch (blue) beginning with the same apparent horizontal velocity as just before the beginning of the shadow zone and another prograde branch with higher apparent velocity (smaller  $dt/dx$ ). Fig. 2.33 is in fact a continuation of the model shown in Fig. 2.30 towards greater depths. One recognizes a low-velocity zone between 12 and 18 km depth. The related ray diagram clearly shows how the rays that are affected by the LVZ jump from an arrival at distance 79 km to 170 km, and then go back to a caustic at 110 km before moving forward again. The related prograde travel-time branches and rays have been color-coded with **green**, **blue** and **violet**. The corresponding  $t_{\text{red}}-x$  plot on the right side of Fig. 2.33 shows nicely the travel-time offset and caustic beyond the shadow zone with two branches: a) retrograde (blue) and b) prograde (violet).

**Fig. 2.33** **Left:** Velocity-depth profile and seismic rays in the crust with a low-velocity zone between  $12 \text{ km} < h < 18 \text{ km}$  depth. The black segment in the velocity-depth curve produces the shadow zone. **Right:** ray diagram and  $t_{\text{red}}-x$  relation for the considered model. The reduction velocity is  $v_{\text{red}} = 5.0 \text{ km/s}$ . Note the additional colored travel-time branches which relate to the seismic rays given in the same color. Green and violet: prograde travel-time curves, blue and red: retrograde travel-time curves. There is a caustic at distance  $x_3$ . Therefore, the end of the shadow has strong amplitudes (courtesy of P. Richards).

An outstanding example for an LVZ, which shows these features very clearly, is the outer core. At the core-mantle boundary the P-wave velocity drops from about 13.7 km/s in the lowermost mantle to about 8 km/s in the liquid outer core. This causes a shadow zone for short-period direct P waves between around 100° and 144°, however slightly “illuminated” by reflected arrivals from the inner-core boundary (PKiKP) and by rays that have been refracted backward to shorter distances (retrograde travel-time branch) due to the strong velocity increase in the inner core (phase PKPdf = PKIKP) (Chapter 11, Fig. 11.73). The travel-time branch PKPab corresponds qualitatively to the blue branch and the branch PKPdf beyond the caustic to the violet branch in Fig. 2.33 (compare with Fig. 2.59). There may exist, however, also low-velocity zones (LVZs) in the crust and in the upper mantle (asthenosphere; see PREM model in Fig. 2.77). LVZs often more pronounced in S-wave velocity than in P-wave velocity because material weakening due to (partial) melting reduces more strongly the shear module  $\mu$  than the bulk module  $\kappa$  [see Eqs. (2.9) and (2.10)].

#### 2.5.3.4 Refraction, reflection, and conversion of waves at a boundary and formation of inhomogeneous waves

So far we have only considered transmission of seismic waves at a boundary. However, generally not all energy is transmitted; parts are reflected or converted. If a P wave hits a boundary between different seismic velocities, four different waves may be generated: a transmitted P wave; a converted transmitted S wave purely polarized in the vertical plane of propagation (SV-wave); a reflected P wave; and a reflected converted SV wave (Fig. 2.34). The geometry of these waves is also governed by Snell's Law:

$$\sin i/v_{p1} = \sin j/v_{s1} = \sin i'/v_{p2} = \sin j'/v_{s2}. \quad (2.17)$$

**Fig. 2.34** An incident P wave at a solid-solid boundary (shown is the case  $v_1 < v_2$ ) generates a reflected and a transmitted P wave and a reflected and transmitted SV wave. Snell's Law governs the angular relationship between the rays of the resultant waves.

In the case of an SH wave hitting the boundary, which is purely polarized in the horizontal plane, there is only a transmitted and a reflected SH wave, but no conversion into P or SV possible. If a single incident wave is split into multiple scattered waves, energy must be partitioned between these waves. Coefficients governing the partitioning between transmitted, reflected, and converted energy will generally depend on the incidence angle of the incoming wave and the *impedance contrast* at the boundary. Impedance is the product of wave velocity and density of the medium. Derivation of the expressions for reflection, transmission, and conversion coefficients is beyond the scope of this book. However, as a telling example, Fig. 2.35 shows for a free surface the four possible P-SV reflection/conversion coefficients (displacement amplitude ratios) against horizontal slowness  $p = \sin i/v_x$  as well as the coefficients for SP and SS, together with the related phase shift, for an incident SV-wave over an extended range of  $p$ . Note the rather large coefficient of 4.1 for SP when  $p = 0.2$  and thus  $i$  for the converted P wave  $90^\circ$ .

**Fig. 2.35 Left:** The four possible reflection/conversion coefficients for a P wave incident on a free surface and either reflected back into the half-space as P or being converted into SV as a function of slowness  $p$ , and these same for an incident SV being either reflected as SV or converted into P. **Right:** The same again for incident SV but for an extended range of slowness  $p$ . In both cases the velocities of  $v_p$  and  $v_s$  in the half-space are 5 km/s and 3 km/s, respectively (courtesy of P. Richards, 2012).

In the left-hand panel of Fig. 2.35 the range for  $p$  is restricted to  $0 \leq p \leq 1/v_p$ . In this case the incidence angle  $i$  is always real and all related waves are homogeneous ones. If, however,  $p > 1/v_p$  then P is an inhomogeneous wave with an imaginary depth component of slowness vector  $\mathbf{s}$ , that is, the horizontal phase velocity,  $p^{-1}$ , is less than the propagation speed of P-waves. The amplitudes of such an inhomogeneous wave decay exponentially with depth in the half-space. If  $p$  is even greater, so that  $p > 1/v_p > 1/v_s$  holds then the associated S wave is an

inhomogeneous wave as well. In section 2.3.1 we had already mentioned, that Rayleigh waves originate from a coupled pair of inhomogeneous P and SV waves that propagate along the surface of a half-space. According to Aki and Richards (2002), all the reflection/transmission coefficients associated with a particular interface will become complex if at least one of the waves set up at the interface by an incident wave is an inhomogeneous wave. An alternative solution to the wave equation, in the case of inhomogeneous waves, is the solution where the amplitudes grow with depth. If there is another interface, then both solutions are present in the layer between two interfaces, if the horizontal slowness is sufficiently great. Note, that in the right-hand panel of Fig. 2.35 SP is a real wave in the slowness range  $0 \leq p \leq 1/v_p = 0.2$  but for larger  $p$  values an inhomogeneous P wave with a strong phase advance is formed.

For more details we relate for a complete treatment to the classic textbook of Aki and Richards (1980 and 2002) and for a condensed overview to Müller (1985) or Shearer (1999). The same applies to the following considerations on seismic energy, amplitudes and phases.

### 2.5.3.5 Seismic rays and travel times in homogeneous models with horizontal and tilted layers

Below we consider a horizontal two-layer model above a half-space. Within the layers and in the half space the wave velocities are constant with  $v_1 < v_2 < v_3$ . The discontinuities between them are of first order, i.e., with instantaneous velocity jumps (see Fig. 2.36). For an incidence angle  $i_1 = i_{cr}^1$ , with  $\sin i_{cr}^1 = v_1/v_2$  and  $v_2 > v_1$ , no wave energy can penetrate into the layer 2, because  $\sin i_2 = 1$  and thus  $i_2 = 90^\circ$ . The angle  $i_{cr}$  is called the *critical angle* because for  $i > i_{cr}$  all energy incident at a first-order discontinuity is totally reflected back into the overlaying layer. However, part of it may be converted. The point in the travel-time curve at which a critically reflected ray (reflection coefficient 1) comes back to the surface is termed the *critical point*  $x_{cr}$ . The travel-time curve has a caustic there. Reflected rays arriving with  $i < i_{cr}$  are termed *pre-critical* (or steep angle) reflections (with reflection coefficients  $< 1$ ), those with  $i > i_{cr}$  as *post-critical*, *super-critical* or *wide-angle reflections*. However, in this case the reflection coefficient becomes a complex number which results in the above discussed phase distortion of over-critical reflections. Note that the travel-time hyperbola of the reflected waves from the bottom of the first layer (red curve) merges asymptotically at larger distances with the travel-time curve of the direct wave in this layer (yellow curve).

Seismic rays incident with  $i_n = i_{cr}^n$  on the lower boundary of layer  $n$  are refracted with  $i_{n+1} = 90^\circ$  into the boundary between the two layers  $n$  and  $n+1$ . They form so-called seismic *head waves* (green and blue rays and travel-time curves, respectively, in Fig. 2.36). Head waves are inhomogeneous boundary waves that travel along the discontinuity with the velocity of layer  $n+1$  and radiate upward wave energy under the angle  $i_{cr}^n$ . The amplitudes of pure head waves decay theoretically with  $1/r^2$ . The full description of this kind of wave, however, is not possible in terms of ray theory but requires a wave-theoretical treatment. In the real Earth, with non-ideal first-order layer boundaries, true *head waves* will hardly exist but rather so-called *diving waves* which slightly penetrate - through the high-gradient zone between the two media - into the underlying high-velocity medium. There they travel sub-parallel to the discontinuity and are refracted back towards the surface under an angle  $\approx i_{cr}$ . In terms of travel time there is practically no difference between a diving wave and a pure head-wave along a first-order velocity discontinuity; diving waves, however, have usually larger amplitudes and can still be observed at much larger distance from the source.

**Fig. 2.36** Schematic local travel-time curves (time  $t$  over distance  $x$  from the source) for a horizontal two-layer model with constant layer velocities  $v_1$  and  $v_2$ , layer thickness  $h_1$  and  $h_2$  over a half-space with velocity  $v_3$ . Other abbreviations stand for:  $t_{ic}^1$  and  $t_{ic}^2$  – intercept times at  $x = 0$  of the extrapolated travel-time curves for the “head-waves”, which travel with  $v_2$  along the intermediate discontinuity between the layers 1 and 2 and with  $v_3$  along the discontinuity between layer 2 and the half-space, respectively.  $x_{cr}^1$  and  $x_{cr}^2$  mark the distances from the source at which the critically reflected rays from the bottom of the first and the second layer, respectively, return to the surface. Beyond  $x_{co}^1$  and  $x_{co}^2$  the head-waves from the bottom of the first and the second layer, respectively, become the first arriving waves ( $x_{co}$  - crossover distance). Rays and their corresponding travel-time curves are shown in the same color. The full **red** (respectively **violet**) travel-time curve relates to the super-critical reflections ( $i > i_{cr}$ ) from the intermediate (respectively lower) discontinuity while the **dotted red** (**violet**) travel-time curve refers to the respective pre-critical ( $i < i_{cr}$ ) steep angle reflections.

In the case of horizontal layering as in Fig. 2.36 the layer and half-space velocities can be determined from the gradients  $dt/dx$  of the yellow, green and blue travel-time curves which correspond to the inverse of the respective layer velocities. When determining additionally the related intercept times  $t_{ic}^1$  and  $t_{ic}^2$  by extrapolating the green and blue curves, or with help of the crossover distances  $x_{co}^1$  and  $x_{co}^2$ , then one can also determine the layer thickness  $h_1$  and  $h_2$  from the following relationships:

$$h_1 = 0.5 x_{co}^1 \sqrt{\frac{v_2 - v_1}{v_1 + v_2}} = 0.5 t_{ic}^1 \frac{v_1 \cdot v_2}{\sqrt{v_2^2 - v_1^2}} \quad \text{and} \quad h_2 = \frac{t_{ic}^2 - 2h_1 \sqrt{v_2^2 - v_1^2} (v_1 \cdot v_2)^{-1}}{2\sqrt{v_3^2 - v_2^2} \cdot (v_2 \cdot v_3)^{-1}}. \quad (2.18)$$

For calculating crossover distances for a simple one-layer model as a function of layer thickness and velocities see Equation (6) in IS 11.1.

In the case where the layer discontinuities are tilted, the observation of travel-times in only one direction away from the seismic source will allow neither the determination of the proper sub-layer velocity nor of the differences in layer thickness. As can be seen from Fig. 2.37, the intercept times, the cross-over distances and the apparent horizontal velocities for the critically refracted head-waves differ when observed down-dip or up-dip from the source although their total travel times to a given distance from the source remain constant. Therefore, especially in controlled-source seismology, *countershot* profiles are deliberately designed so as to identify changes in layer dip and thickness.

**Fig. 2.37** Schematic travel-time curves for direct waves and head waves in a single-layer model with inclined lower boundary towards the half-space. Note the difference between up-dip and down-dip observations (“countershot profile”).  $t_{ic}^-$  and  $v_2^-$  are the intercept time and related apparent velocity of the down-dip head wave,  $t_{ic}^+$  and  $v_2^+$  the respective values for the up-dip travel-time curve.

For the considered simple one-layer case in Fig. 2.37 the dip angle  $\phi$  and the orthogonal distance  $h_1$  to the layer boundary underneath the seismic source on the left can be determined from the following relations:

$$\phi = \frac{1}{2} [\sin^{-1} (v_1/v_2^-) - \sin^{-1} (v_1/v_2^+)] \quad (2.19)$$

and

$$h_1 = \frac{1}{2} t_{ic}^- [v_1 v_2 / \sqrt{(v_2^2 - v_1^2)}]. \quad (2.20)$$

### 2.5.3.6 Wiechert-Herglotz inversion

In the case of velocity  $v = f(z)$  increasing monotonously with depth  $z$ , as in Fig. 2.29, a continuous travel-time curve is observed because all rays return back to the surface. The epicenter distance  $x = D$  of their return increases with decreasing  $p$ , i.e.  $dx/dp < 0$ . The related travel-time curve, with  $dt/dx > 0$  is termed *prograde*. In this case an exact analytical solution of the inverse problem exists, i.e., when knowing the apparent horizontal velocity  $c_x(D) = v_o/\sin i_o = dD/dt$  at any point  $D$ , we know the velocity  $v_{tp}$  at the turning point of the ray that returns to the surface at  $D$ . Thus one can calculate the depth  $z(p) = z_{tp}$  of its turning point. The following relations were developed by Wiechert and Herglotz for the return distance  $D(p)$  and the depth of the turning point  $z(p)$  of a given ray (see Wiechert and Geiger, 1910):

$$D(p) = 2 \int_0^{z(p)} \frac{p v(z)}{\sqrt{1 - p^2 v(z)^2}} dz \quad (2.21)$$

and

$$z(p) = \frac{1}{\pi} \int_0^D \cosh^{-1} \frac{c_x(D)}{c_x(x)} dx \quad (2.22)$$

Note, however, that the velocity  $v_{tp}(p)$  determined from  $dx/dt$  at distance  $x = D$  does always relate to the respective depth half way between source and station! Nevertheless, practically all one-dimensional Earth models have been derived this way assuming that lateral variations of velocity are negligible as compared to the vertical velocity variations.

## 2.5.4 Amplitudes and phase distortions

### 2.5.4.1 Energy and amplitudes of seismic waves

The energy density  $E$  contained in a seismic wave may be expressed as the sum of kinetic ( $E_{kin}$ ) and potential ( $E_{pot}$ ) energy densities :

$$E = E_{kin} + E_{pot} \quad (2.23)$$

The potential energy results from the distortion of the material (strain; see. Figs. 2.2) working against the elastic restoring force (stress) while the kinetic energy density is

$$E_{kin} = \frac{1}{2} \rho a_v^2, \quad (2.24)$$

where  $\rho$  is the density of the material,  $a_v = A \omega \cos(\omega t - kx)$  is the ground-motion particle velocity, with  $A$  - wave amplitude,  $\omega$  - angular frequency  $2\pi f$  and  $k$  - wavenumber. Since the mean value of  $\cos^2$  is  $\frac{1}{2}$  it follows for the average kinetic energy density  $\bar{E}_{kin} = \frac{1}{4} \rho A^2 \omega^2$ , and with  $E_{kin} = E_{pot}$  in case of an isotropic stress-strain relationship in a non-dispersive (closed) system for the average energy density

$$\bar{E} = \frac{1}{2} \rho A^2 \omega^2. \quad (2.25)$$

The energy-flux density per unit of time in the direction of wave propagation with velocity  $v$  is then

$$E_{flux} = \frac{1}{2} v \rho A^2 \omega^2 \quad (2.26)$$

and the total energy-flux density  $E_{flux}$  through a small surface area  $dS$  of the wavefront bounded by neighboring rays which form a *ray tube*

$$E_{flux} = \frac{1}{2} v \rho A^2 \omega^2 dS. \quad (2.27)$$

When considering only waves with wavelengths being small as compared to the inhomogeneities of the medium of wave propagation (high-frequency approximation), then we can assume that the seismic energy only travels along the rays. According to the energy conservation law, the energy flux within a considered ray tube must remain constant although

the surface area  $dS$  of the wavefront related to this ray tube may vary along the propagation path due to focusing or defocusing of the seismic rays (e.g., Figs. 2.30 and 2.33). Considering at different times two surface patches of the propagating wavefront  $dS_1 \neq dS_2$ , which are bounded by the same ray tube, and assuming that  $v$  and  $\rho$  are the same at these two locations then

$$A_1/A_2 = (dS_2/dS_1)^{1/2}, \quad (2.28)$$

i.e., the amplitudes vary inversely as the square root of the surface area of the wavefront patch bounded by the ray tube. Thus amplitudes increase due to ray focusing, which is particularly strong at caustics (see 2.5.3.2) and decrease when the wavefront spreads out (e.g., Figure 3a in IS 2.1).

Also, for a spherical wavefront (e.g., body-wave propagation in a homogeneous isotropic medium) the surface area grows with  $r^2$  and for a cylindrical wavefront (e.g., for surface waves) with distance  $r$ . Accordingly, the wave-amplitude decay is in the former case  $\sim r$  and in the latter case  $\sim \sqrt{r}$ . This difference in *geometrical spreading* is the main reason for the domination of surface wave amplitudes in seismic records of shallow events (e.g., Fig. 2.12 and Fig. 3.34).

However, wave amplitudes will also change, even in the absence of geometrical spreading, when density  $\rho$  and velocity  $v$  vary at different locations along the ray path. We then get

$$A_1/A_2 = [(\rho_2 v_2)/(\rho_1 v_1)]^{1/2}. \quad (2.29)$$

The product  $\rho v$  is termed the *impedance* of the material and  $(\rho_2 v_2)/(\rho_1 v_1)$  is the *impedance contrast* between the two adjacent media  $m_1$  and  $m_2$ . The latter largely controls the reflection and transmission coefficients at the media discontinuity. From Eq. (2.29) it follows that seismic amplitudes will increase as waves propagate into media of lower density and wave propagation velocity. This has two important implications. On the one hand, seismic stations on hard bedrock tend to record smaller amplitudes and thus to slightly underestimate event magnitudes as compared to stations on average or soft-soil conditions. On the other hand, ground shaking from strong earthquakes is usually more intense on top of unconsolidated sediments as compared with nearby rock sites. Additionally, reverberations and resonance within the unconsolidated near-surface layers above the basement rocks may significantly amplify the amplitudes at soft-soil sites. This may increase significantly local seismic hazard.

In this context one should mention that in earthquake records amplitudes of S waves are at comparable period on average about five times larger than those of P waves (see Fig. 2.3 and Figure 1 in EX 3.4). This follows from Eq. (3.2) in Chapter 3 or from the far-field term of the Green's function when modeling earthquake shear sources [see Eq. (24) in the IS 3.1], taking into account that  $v_P \approx v_S \sqrt{3}$ . This would correspond to an average ratio between S-wave and P-wave energy radiation of about 25. The ratio, however, depends on the specifics of the considered source mechanisms. Published numbers vary between about 13.7 and 40.5 (e.g., Aki and Richards, 1980; Boatwright and Fletcher, 1984; Boatwright and Quin, 1986, Duda and Yanovskaya, 1993), yet empirical data hint to values closer to the lower bound. The S-/P-wave amplitude ratio in individual seismic records additionally depends strongly on the position (azimuth and distance) of the station with respect to the radiation pattern and directivity of the source (see Chapter 3, section 3.4). For explosions, however, the average ratio is usually much smaller and may become even less than 1, depending also on frequency (see Fig. 2.38).

**Fig. 2.38** Typical records of a local earthquake ( $D = 125$  km) and a local explosion ( $D = 149$  km) in broadband (top traces) and high-frequency filtered records (middle and bottom traces). According to data from Kim et al. (1993), *Geophysical Research Letters*, **20**, 1507–1510.

Also, the periods of S waves tend to be longer than those of P waves, at least by a factor of  $\sqrt{3}$ , due to the differences in wave propagation velocity and the related differences in the corner frequencies of the P- and S-wave source spectrum.

For shallow earthquakes the amplitudes of surface waves are generally much larger than those of body-waves (see Fig. 2.12 and many more examples in DS 2.1-2.2), whereas the amplitude ratios of primary P and S waves with respect to their secondary (often multiple) reflected and converted waves varies strongly according to distance and incidence-angle dependent reflection/conversion coefficients (e.g., Fig. 2.35). No simple rules can be given and proper phase identification on the basis of relative travel-times, slowness, amplitude and period relationships requires a lot of practical experience.

For overview papers with many references on the calculation of released seismic wave energy, based on the integration of squared broadband velocity records or moment rate spectra, see IS 3.6 by G. Choy in this Manual, section 3.2.7.2 in Chapter 3 and Di Giacomo and Bormann (2011).

#### 2.5.4.2 Wave attenuation

Amplitudes of seismic waves are not only controlled by geometrical spreading, focusing/defocussing and by the reflection and transmission coefficients at discontinuities. Wave amplitudes may also be reduced because of energy loss due to viscoelastic material behavior and thus internal friction and heat generation during wave propagation. This effect is called *intrinsic attenuation*. Also, scattering of energy at heterogeneities along the travel paths with scale lengths in the order of wavelength may reduce amplitudes of seismic waves, change the shape of the initial cycle of a body wave pulse as well as of the motion immediately following the initial cycle, termed *coda*, with high-frequency energy being

transferred into the coda (see Fig. 2.44). The separation of intrinsic and scattering attenuation is not trivial. For a review see Cormier (2009). In the case of *scattering attenuation*, however, the integrated energy in the total wavefield remains constant, while *intrinsic attenuation* results in loss of mechanical wave energy, e.g., by transformation into heat. The wave attenuation is usually expressed in terms of the dimensionless *quality factor*  $Q$

$$Q = 2\pi E/\Delta E \quad (2.30)$$

where  $\Delta E$  is the dissipated energy per cycle. Thus,  $Q$  is a measure of the area contained in the hysteresis loop of a stress-strain cycle. **Large energy loss means low  $Q$  and vice versa, i.e.,  $Q$  is inversely proportional to the attenuation.** In a simplified way we can write for the decay of source amplitude  $A_0$  with distance  $x$

$$A = \frac{A_0}{x^n} e^{-\frac{\omega t}{2Q}} = \frac{A_0}{x^n} e^{-\frac{\pi x}{QTv}} = \frac{A_0}{x^n} e^{-\frac{\omega x}{2Qv}}, \quad (2.31)$$

with  $A_0/x^n$  – the geometrical spreading term,  $\exp(-xt/2Q) = \exp(-\pi/QTv)$  – the attenuation term,  $\omega$  – angular frequency  $2\pi/T$ ,  $T$  – period of wave,  $t$  – travel time,  $v$  – propagation velocity of wave, and  $n$  – exponential factor controlled by the kind of geometric spreading. According to experimental data,  $n$  varies between about 0.3 and 3, depending also on the type of seismic wave and distance range considered.

In ray theoretical methods, attenuation may be modeled through the use of the parameter  $t^*$  that is defined as the integrated value of the travel time divided by  $1/Q$

$$t^* = \int_{\text{path}} \frac{dt}{Q(\vec{r})}, \quad (2.32)$$

where  $\vec{r}$  is the position vector. Accordingly, we can then write Eq. (2.31) as

$$A(\omega) = A_0(\omega) e^{-\omega t^*/2}. \quad (2.33)$$

Note, that P-wave attenuation  $Q_\alpha$  and S-wave attenuation  $Q_\beta$  differ. They are related to the shear attenuation  $Q_\mu$  and the bulk attenuation  $Q_\kappa$  by the relationships

$$Q_\beta = Q_\mu \quad \text{and} \quad 1/Q_\alpha = (4/3)(\beta/\alpha)^2/Q_\mu + [1 - (4/3)(\beta/\alpha)^2]/Q_\kappa. \quad (2.34)$$

with P-wave velocity  $\alpha = v_p$  and S-wave velocity  $\beta = v_s$ . In the Earth shear attenuation is much stronger than bulk attenuation. While  $Q_\mu$  is smallest (and thus shear attenuation strongest) in the upper mantle and zero in the outer core (see DS 2.1),  $Q_\kappa$  is generally assumed to be close to infinite, except in the inner core. While the P- and S-wave velocities are rather well known and do not differ much between different Earth models, the various model assumptions with respect to  $Q_\alpha$  and  $Q_\beta$  as a function of depth still differ significantly (see Fig. 2.79). According to the PREM model,  $Q_\mu$  is 600 for less than 80 km depth. It then drops between 80 and 220 km to 80, increases to 143 from 220 to 670 km, and is 312 for the lower mantle below 670 km depth. For pure viscoelastic attenuation in Poisson solid  $t_s^*$  is about 4 times larger than  $t_p^*$ . However, there are indications that this difference decreases for higher

frequencies because apparent  $1/Q_P$  approaches  $1/Q_S$  at frequencies  $> 1\text{Hz}$ . This hints to an increasing effect of scattering attenuation on P waves at higher frequencies (Cormier, 2009).

One of the important questions in this context is, whether the quality parameter  $Q$  itself depends on frequency or not. According to Dziewonski and Anderson (1981), seismological observations are consistent with the hypothesis of  $Q$  being independent on period only down to periods 5-10 s but that they provide no information about attenuation of the waves at periods less than 5 s. However, experimental studies (Berckhemer et al., 1982; Ulug and Berckhemer, 1984) showed that within the absorption band  $Q$  varies with frequency. Choy and Cormier (1986) proved this by direct measurement of the mantle attenuation operator from broadband P and S waves, thus resolving the difference between results from the normal-mode long-period community and the high-frequency (e.g., nuclear monitoring) communities. In order to explain the amplitudes of seismic spectra in the 1-10 Hz frequency band, it was necessary to assume an increase of  $Q$  with frequency, even when assuming white source spectra (Cormier, 2009). Therefore, Duda and Yanovskaya (1993) calculated a hybrid set of theoretical spectral  $\log A$ - $\Delta$  curves for P-waves (upper diagram in Fig. 2.39). It rests on the frequency independence of the  $Q$  in the PREM model (see Fig. 2.79 and DS 2.1) down to 5 s but introduces for shorter periods a frequency-dependence of  $Q$  on the basis of the absorption-band model proposed by Liu et al. (1976) and Anderson et al. (1976), assuming a relaxation time of 0.16 s. This has the effect that at 1 Hz  $Q^{-1}$  has already only half the value of the frequency independent  $Q^{-1}$  in the PREM model.

According to the “hybrid” PREM model no strong increase of frequency-dependent absorption has to be expected for periods below 4 s and the difference in  $\delta \log A$  of spectral amplitudes at 2 s and 0.5 s, which covers the main range of periods at which the short-period body-wave magnitude  $m_b$  is measured, is only about 0.3. When investigating regional variations and frequency-dependence of anelastic attenuation in the mantle under the United States in the 0.5-4 Hz band Der et al. (1982) found about the same difference for the respective spectral P-wave amplitudes, whereas the difference for S-wave  $\log A$  was about 1. In contrast, recent investigations by D. Di Giacomo (personal communication 2011) yielded

on the basis of the frequency-independent AK135 and PREM Q-models as well as empirically much larger attenuation-caused differences of spectral amplitudes between 2 s and 0.5 s, ranging between about 1.8 to 2.2 log-units (see Fig. 2.40). This compares even better with the calculations by Duda and Yanovskaya (1993) for the alternative ABM model proposed by Anderson and Given (1982) in which the parameters of the absorption-band vary with depth in the Earth (Fig. 2.39, lower diagram), resulting in  $\delta \log A$  for periods of 2 s and 0.5 s in the distance range  $20^\circ < \Delta < 100^\circ$  between about 1.2 and 2.6 log-units. Such large differences between currently existing attenuation models are not yet fully understood or supported by high-quality empirical data and the way in which the latter are processed and interpreted, usually again on the basis of simplified model assumptions. This requires more thorough specialized in-depth studies in future.

For periods longer than about 4 s, however, all the here presented different models yield about the same results in agreement with the assumption of frequency-independent Q. Most importantly, however, is to realize that theoretical calculations based on global 1-D models can at best describe and allow to account for the average trend of amplitude decay with distance due to geometric spreading and inelastic attenuation but not for the very significant scatter of the real data in the order of about  $\pm 0.5$  to 0.7 log-units (see Fig. 2.40). The latter is mainly controlled by local effects at the station sites such as spectral amplification due to soft-layer cover over bedrock (see Chapter 14), focussing and de-focussing effects due to 3-D velocity and topographic anomalies and/or source radiation differences into the direction of the considered different station azimuth at comparable distances, rather than by local or regional anomalies in inelastic attenuation.

**Fig. 2.40** Displacement spectral amplitudes at 0.5 s (2 Hz, light gray triangles), 1 s (1 Hz, black circles) and 2 s (0.5 Hz, gray diamonds) for the  $M_w = 7.9$  Wenchuan, China, earthquake of 2008 May 12, superimposed to the theoretical spectral amplitude decay functions for the same frequencies for the AK135 model (median, 25<sup>th</sup> and 75<sup>th</sup> percentile in solid and dashed red lines, respectively) and the PREM model (median, 25<sup>th</sup> and 75<sup>th</sup> percentile in solid and dashed violet lines, respectively). An arbitrary offset has been added to the theoretical curves to make easier the comparison with the real data. (Courtesy of D. Di Giacomo, 2011).

According to Fig. 2.40 the AK135Q model curves seem better than the ones calculated with the PREM model to agree towards higher frequencies with the observed average increments in frequency-dependent attenuation, although both models assume **no** frequency dependence of  $Q$ . Thus, the significance of the absorption-band effect and the necessity of accounting for a frequency dependence of  $Q$  for periods  $0.5 \text{ s} \leq T < 4 \text{ s}$  is still difficult to prove with available noisy empirical data.

In practice there is another difficulty, namely to separate intrinsic (inelastic)  $Q$  and scattering  $Q$ . Particularly in local earthquake records, which are strongly affected by scattering on crustal inhomogeneities, scattering  $Q$  dominates. Scattering  $Q$  is usually determined from the decay of coda waves following  $S_g$  and  $S_mS$  onsets (e.g., Fig. 2.47) and is called accordingly  $Q_c$ . For an elaborate discussion of these topics see Aki and Richards (1980; pp. 170-182) and for a review about  $Q$  of the Earth from crust to core Romanovicz and Mitchell (2007).

Also note that  $S$  waves are much stronger attenuated than  $P$  waves (see also  $Q$  models and formulas in DS 2.1), thus filtering out more strongly the higher frequencies. Moreover,  $S$  waves do not propagate in the fluid outer core because of vanishing shear module (see Fig. 2.79). Therefore, no direct  $S$  waves are observed beyond  $100^\circ$  epicenter distance (with the exception of long-period  $S$  diffracted around the core-mantle boundary; see Fig. 2.60).

The discussed differences in amplitude-distance relationships have to be compensated by wave-type dependent calibration functions in order to be able to derive comparable magnitude values for seismic events based on amplitude readings from different types of seismic waves (see 3.2). However, for teleseismic body- and surface-wave magnitudes, based on measuring the ratio  $(A/T)$ , or directly ground motion velocity (see IS 3.3), the effect of exponential frequency-dependent attenuation on  $A$  is reduced by multiplying  $A$  with  $f = 1/T$ , making the related calibration functions less dependent on variations in period.

### 2.5.4.3 Phase distortions and Hilbert transform

As shown in Fig. 2.27 seismic rays will curve in the case of a vertical velocity gradient and thus seismic wavefronts will no longer be planar. Nevertheless, locally, between adjacent rays defining a *ray tube*, the wavefront still can be considered as a plane wavefront. In the case of strong gradients, retrograde travel-time branches will develop because rays bend stronger, cross each other and the wavefront folds over itself at the turning point (Fig. 2.41). Accordingly, a local plane wavefront traveling through a strong vertical velocity gradient will experience a constant, frequency-independent  $\pi/2$  phase advance at the turning point. The envelope of turning points of these crossing bended rays is termed an *internal caustic surface*. Because of the  $-\pi/2$  phase shift the up-going plane wave is the *Hilbert transform* of the down-going wave. More generally, whenever a ray has a non-pure minimum ray path (see 2.5.2) it touches such a caustic. Consequently, its pulse shape is altered (see Fig. 2.42). Example: The Hilbert transform of a pure sine wave is a cosine wave. In the case of seismic waves this phase shift by  $-\pi/2$  has to be applied to each single frequency represented in the seismic pulse. This results in the known pulse shape alterations.

**Fig. 2.41** In a medium with steep vertical velocity gradient, seismic rays with larger take-off angles from the source turn back towards the source thus forming a retrograde branch of a travel-time curve. The crossing of ray paths forms an internal caustic surface that produces a  $-\pi/2$  phase shift in the waveforms (according to Choy and Richards, 1975; modified from Shearer, Introduction to Seismology, 1999; with permission of Cambridge University Press).

**Fig. 2.42 Left:** A typical seismic pulse; **Right:** Its Hilbert transform.

Generally, in the case of a steep velocity gradient producing a retrograde travel-time branch, ray theory predicts that seismic wave arrivals along this branch are Hilbert transformed compared to the prograde branches. One should note, however, that also in case of relatively weak vertical velocity gradients, which do not produce a retrograde travel-time branch for the direct wave, the related reflected phase might nevertheless be Hilbert transformed (see Fig. 2.43 for PP waves). On the other hand, when the gradient becomes too steep, or in the case of a first-order velocity step discontinuity, the post-critical reflection coefficients for such an interface involve a continuous change in phase with ray angle. The phase shift may then acquire any value other than a constant  $-\pi/2$  phase shift.

Without exception, all the distorted waveforms bear little or no resemblance to the original waveforms. Accordingly, neither their onset times (first arrival of energy) nor the relative position of peaks and troughs of the distorted waveforms appear at the times that are theoretically predicted by ray theory. This biases onset-time picking, related travel-time determinations as well as waveform correlations between primary and Hilbert transformed phases. Therefore, modern digital data-analysis software can routinely apply the inverse Hilbert transform to phases distorted by internal caustics. The following major teleseismic body-wave phases are Hilbert transformed: PP, PS, SP, SS, PKPab, pPKPab, sPKPab, SKKSac, SKKSdf, P'P', S'S'ac. For the nomenclature of these phases and their travel paths see Figures 2.57-2.58 and IS 2.1). However, many phases pass caustics several times in the Earth and then the final pulse shapes are the sum of all internal caustic effects.

**Fig. 2.43** Ray paths for the surface reflected phase PP. Note that the rays after the reflection points cross again and form an internal caustic. Accordingly, PP is Hilbert transformed relative to P and additionally has an opposite polarity (phase shift of  $\pi$ ) due to the surface reflection (from Shearer, Introduction to Seismology, 1999; with permission from Cambridge University Press).

#### 2.5.4.4 Effects not explained by ray theory

As mentioned above, ray theory is a high-frequency approximation that does not cover all aspects of wave propagation. Although detailed wave-theoretical considerations are beyond the scope of this Manual we will shortly mention three major phenomena that are of practical importance and not covered by ray theory.

##### *Head waves*

As mentioned in 2.5.4.1, seismic waves impinging at a discontinuity between the layers  $n$  and  $n+1$  with  $v_n < v_{n+1}$  under the critical incidence angle  $i_c$  with  $\sin i_c = v_n/v_{n+1}$  are refracted into this discontinuity with the angle  $i_{n+1} = 90^\circ$ . There they travel along (or just below) this discontinuity with the velocity  $v_{n+1}$  of the lower faster medium. Such kind of *inhomogeneous* waves (see section 2.5.3.4) are usually referred to as *head waves*. They have the unique property to transmit energy back into the upper medium at exactly the critical angle  $i_c$ , however with amplitudes which decay with distance  $\sim 1/r^2$ . Therefore, the amplitudes of true head-waves are rather small as compared to those of direct, reflected or converted waves. The travel-time curve of a head wave is a straight line with the slope of  $1/v_{n+1}$  (see Fig. 2.36). This provides a convenient and direct measure of the sub-discontinuity velocity. Head waves are of particular importance for crustal studies and in the analysis of seismic records from local and regional seismic events (see 2.6.1).

##### *Seismic Diffraction*

Diffraction, analog to optics, is the phenomenon of transmission of energy by non-geometric ray paths. In optics, the classic example is the diffraction of light “leaking” around the edge of an opaque screen. In seismology, diffraction occurs whenever the radius of curvature of a reflecting interface approaches the order of wavelength of the propagating wave. Seismic diffraction is important for example in steep-angle reflection data in the presence of sharp boundaries. But there are also long-period diffracted waves such as Pdif and Sdif which are “bended” around the core-mantle boundary into the core shadow zone beyond about  $100^\circ$  epicenter distance. Only little short-period P- and S-wave energy is observed in this shadow zone. In fact, the edge of a discontinuity/impedance contrast acts like a secondary source according to Huygens's principle and radiates energy forward in all directions.

Diffractions can also be understood from the standpoint of *Fresnel zones*. This concept states that waves are not only reflected at a considered point of the discontinuity (like a seismic ray) but also from a larger surrounding area. The radius of the so-called first Fresnel zone is about  $\frac{1}{2}$  wavelengths around a considered ray arriving at a station, i.e., the range within which reflected energy might interfere constructively. The wavelength-dependent width of this Fresnel zone also determines the geometrical resolution of objects/impedance contrasts that can be at best achieved by seismic (or optical) methods.

Since the real Earth may significantly deviate from simplified global one-dimensional models, scattering and diffraction effects render not only amplitudes but also travel times of more low-frequency waves sensitive to the 3-D structure off the seismic rays. This has to be taken into account when making use of recent developments of automated travel-time measurement techniques which use cross-correlation of observed body wave phases in digital broadband records with the corresponding synthetic phases possible in spherical Earth. Marquering et al. (1999) showed that for an SS wave observed at an epicenter distance of  $80^\circ$ , near-surface heterogeneities situated more than  $15^\circ$  from the bounce point at  $40^\circ$  can exert a significant influence upon the travel time of an SS wave. They conclude that geometrical ray theory, which has been a cornerstone of seismology for about a century and proven useful in most practical applications, including earthquake location and tomography, is, however, valid only if the scale length of the 3-D heterogeneities is much greater than the seismic wavelengths. In other words, the validity of ray theory is based on a high-frequency (short-period) approximation. However, intermediate-period and long-period seismic waves, with wavelength of the order of 100 – 1000 km, already have comparable scale lengths with 3-D anomalies in current global tomographic models. When investigating smaller 3-D structures and applying new methods of waveform correlation, these wave-theoretical considerations gain growing importance, probably even in future observatory routines. In this context we refer to section 2.7.2 on 3-D Earth models and their use in event location and to the establishment, in 2012, of an international “Working Group on the Utilization of Global 3-D Models for Seismic Observatory Applications” by the IASPEI Commission on Seismic Observation and Interpretation (CoSOI).

### ***Scattering of seismic waves***

Often the primary arrivals are followed by a multitude of later arrivals that can not be explained by simple 1-D models. The complex wave train following the primary arrival(s), often with exponentially decaying amplitudes, is called coda (Figs. 2.44 and 2.45). Coda arrivals are produced by scattering, that is, the wavefield's interaction with small-scale heterogeneities. Heterogeneity at different length scales is present almost universally inside the Earth. Seismic coda waves can be used to infer stochastic properties of the medium, i.e., scale the amplitude of the average heterogeneities, to estimate coda  $Q_c$  which is particularly needed for correcting source spectra prior to deriving spectral source parameters from records of local events (see exercise EX 3.4), and to estimate earthquake magnitude (see Chapter 3). Moreover, according to Rautian et al. (2007) there is great potential in using the later part of the coda for spectral source parameter estimation such as seismic energy, seismic moment, apparent stress, etc. by means of multi-bandpass filtering, first proposed by Rautian and Khalturin (1978).

**Fig. 2.44** Clearly developed coda waves of the high-pass filtered (0.7 to 4 Hz) filtered record of a local earthquake on 26.07.2000 near Limburg/Lahn in Germany ( $D = 29$  km,  $M_l = 3.5$ ) at station TNS.

**Fig. 2.45** Three-component seismogram of a local, 100 km deep earthquake recorded at a portable station on the active volcano Lascar in northern Chile. The P-wave arrival is followed by coda waves produced by heterogeneous structure in the vicinity of the volcano (courtesy of B. Schurr, 2001).

## 2.6 Seismic phases and travel times in real Earth (P. Bormann)

Seismic body waves propagate three-dimensionally and are more strongly affected than surface waves by refraction, reflection and mode conversion at the main impedance contrasts in the radial direction of the Earth. This gives rise, with growing distance, to the appearance of more and more secondary seismic body-wave phases following the direct P- and S-wave arrivals in seismic records (e.g. Fig. 2.25). And since body waves show no dispersion in the considered frequency range these phases can usually be well observed and discriminated from each other as long as their travel-time curves do not overlap.

All of these secondary phases have a special story to tell about the geometrical and physical properties of the discontinuities which they encountered during their travel through the Earth's interior and which have shaped their waveforms and influenced their amplitude and frequency content. Therefore, the proper identification and parameter or waveform reporting about later phases in seismic records to relevant data centers is an important duty of seismological observatories. In addition, the complementary use of secondary phases significantly improves the precision and accuracy of seismic event locations, their source depth in particular (see Figure 7 in IS 11.1 and section 2.6.3). In the following, we will introduce the main types of seismic body-wave phases that can generally be observed at local, regional and teleseismic distance ranges. They should be identified, analyzed and reported by

seismic observatories or data analysis centers. Basic features of their travel-time curves, polarization, waveforms and frequency range of observation, which can guide their identification, will be presented.

### 2.6.1 Seismic phases and travel times from local and regional events

Seismic waves arriving at stations at local distances of up to about 150 km or regional distances of up to about 15° (1° = 111.2 km) from the seismic source have traveled exclusively or dominantly through the crust or the sub-crustal uppermost mantle. The crust varies strongly in its thickness (see Fig. 2.11), petrologic composition and internal structure due to folding and faulting processes in the past. The resulting strong heterogeneities in physical properties at scale length of several decameters to several km cause intensive scattering of P and S waves in the typical frequency range for the recording of near seismic events (about 0.5 to 50 Hz). Therefore, primary wave onsets are usually followed by signal-generated noise or coda waves that make it difficult to identify later seismic phases reflected or refracted from weaker intra-crustal discontinuities. It is usually only the significant velocity increase of about 20% at the base of the crust towards the upper mantle (*Mohorovičić discontinuity*, or *Moho* for short), which produces first or later wave onsets besides the direct P and S waves that are strong enough to be recognizable above the ambient or signal-generated noise level. Only in some continental regions may an intermediate discontinuity, named the *Conrad discontinuity* after its discoverer, produce recognizable critically refracted (Pb = P\*; Sg = S\*) or reflected waves (see Fig. 2.46). Accordingly, for purposes of routine seismological observatory practice, it is usually sufficient to represent the crust as a horizontal one-layer model above the half-space (upper mantle).

Both of the widely used global 1-D Earth velocity models, IASP91 by Kennett and Engdahl (1991) and AK135 by Kennett et al. (1995) assume a homogeneous 35 km thick two-layer crust with the intermediate crustal discontinuity at 20 km depth (see DS 2.1). The respective average velocities for the upper and lower crust and the upper mantle are for P waves 5.8 km/s, 6.5 km/s and 8.04 km/s, and for S waves 3.36 km/s, 3.75 km/s and 4.47 km/s, respectively. The *impedance contrast* at the Conrad discontinuity and the Moho is about 1.3. Fig. 2.46 is a simplified depiction of such a two-layer crust and of the seismic rays of the main crustal/upper mantle phases to be expected. These are: Pg, Sg, Pb, Sb, Pn, Sn, PmP and SmS. For detailed definition of the phase names see IS 2.1 or Storchak et al. (2003 and 2011).

**Fig. 2.46** A simplified model of the crust showing the ray traces of the main “crustal phases” observed for near (local and regional) earthquakes. Note: P\* = Pb and S\* = Sg.

The apparent horizontal velocity of the reflected PmP and SmS waves varies with distance according to their changing incidence angle on the surface. Their travel-time branches form hyperbolae that approach asymptotically the travel-time curves for Pg and Sg (or Pb and Sb) with increasing distance (see Fig. 2.47). Note that Pn, if a head wave, has usually smaller amplitudes than Pg and Sg, at least for distances up to about 300 km. Pn can be usually identified above the noise level only when it becomes the P-wave first arrival. At larger distances, because of the stronger attenuation of upper crustal Pg and Sg and with Pn and Sn being less attenuated as typically upper mantle diving phases, Pn and Sn may become clear P and S first arrivals (see Fig. 2.17). Beyond the critical point (at about 70-80 km distance for an average crust) the super-critically reflected waves PmP and SmS have generally the largest amplitudes, however, arriving always closely after Pg and Sg, their onset times can usually not be picked reliably enough as to be of value for earthquake location. Therefore, these phases are usually not explicitly reported in routine observatory practice. However, reporting of Pg, Sg, Pn and Sn, if recognizable, is a must. This also applies to the reporting of the maximum amplitudes in records of near seismic events for the determination of local magnitudes  $M_L$  (see Chapter 3, section 3.2.4). Depending on source depth too, this amplitude maximum may be related to Sg/SmS, Lg, or Rg (see Figs. 2.17, 2.18 and 2.47). A simple average local travel-time curve for a single-layer crust in Central Europe had been derived from related reliable phase observations at European observatories from an earthquake in Hungary decades ago. It is depicted in Fig. 2.48 and proved to be a suitable single-layer crust approximation for routine analysis, phase identification and location of seismic events in the considered area (see EX 11.1). The crustal and sub-Moho velocity data given in DS 2.1 for IASP91 and AK 135, respectively, would permit to calculate a similar global average travel-time curve.

**Fig. 2.47** Records (above) of two regional earthquakes of Oct. 9, 1986 at Sierre (left) and of July 7, 1985 at Langenthal, Switzerland together with the calculated reduced travel-time curves (middle) and ray-tracing crustal models which best fit the observations (below), redrawn and complemented from Kulháněk (1990), *Anatomy of Seismograms*, plate 4, pp. 83-84, © (with permission from Elsevier Science).

**Fig. 2.48** Empirically determined average travel-time curves for the phases Pn, Pg, Sn, Sg and Lg observed at distances up to 400 km, assuming a single-layer crust in Central Europe.

However, crustal travel-time curves based on a global velocity model may not be representative at all for certain regions and may serve as a starting model only to work with. It is one of the main tasks of operators of local and regional seismic networks to derive from their own carefully analyzed data of near events not only local/regional magnitude calibration functions (see 3.2.4.3 and Table 2 in DS 3.1) but also average local/regional 1-D travel-time curves. The latter will not only allow significantly improved seismic event locations but may serve also as starting models for tomographic studies of crustal heterogeneities and the derivation of 3-D velocity models.

Fig. 2.47 above shows real short-period seismic network records of two local earthquakes in Switzerland in the distance range between about 10 km and 180 km along different profiles together with the modeling of their reduced travel-time curves and inferred structural profiles. While one event was at a depth of only 5 km, the other event was about 30 km deep. The first one was observed by stations situated up-dip while the latter event was observed down-dip. The striking differences in the shape and gradient of the travel-time curves and in the crossover distance between Pg and Pn, in particular, are obvious. In the case of the deeper event near to the Moho, Pn becomes the first arrival beyond 70 km distance, whereas for the shallower event Pn outruns Pg only at more than 130 km epicenter distance. In both cases Pg (Sg) and/or PmP (SmS) are the prominent P and S arrivals. The Pn first arrivals are relatively small. No Pb, Sb or reflected waves from a mid-crustal discontinuity are recognizable in Fig. 2.47. Note, however, depending on the orientation of the earthquake rupture and thus of the related radiation characteristic of the source, it may happen that a maximum of energy is radiated in the direction of the Pn ray and a minimum in the direction of the Pg ray. Then the usual relationship  $A_{Pn} < A_{Pg}$  may be reversed (examples are given in Chapter 11, section 11.5.1).

Misinterpretation of Pn as Pg or vice versa may result in large errors of event location. Therefore, one should have at least a rough idea at which distance in the region under study, depending on the average crustal thickness and velocity, one may expect Pn to become the first arrival. A “rule-of-thumb” for calculating the crossover distance  $x_{co}$  is given in Eq. (6) of IS 11.1. For an average single-layer crust and a surface source,  $x_{co} \approx 5 z_m$  with  $z_m$  – Moho depth. However, as demonstrated with Fig. 2.47,  $x_{co}$  is only about half as large for near Moho earthquakes and also the dip of the Moho and the direction of observation (up- or down-dip) do play a role. Yet, lower crustal earthquakes are rare in a continental (intraplate) environment. Mostly they occur in the upper crust. Rules-of-thumb for calculating the source distance from the travel-time differences Sg-Pg and Sn-Pn are:

$$\text{hypocenter distance } d \text{ [in km]} \approx \Delta t(\text{Sg-Pg}) \text{ [in s]} \times 8 \text{ (near range only)} \quad (2.35)$$

$$\text{epicenter distance } D \text{ [in km]} \approx \Delta t(\text{Sn-Pn}) \text{ [in s]} \times 10 \text{ (in Pn-Sn range } < 15^\circ) \quad (2.36)$$

Sometimes, very strong onsets after Pg, well before Sn or Sg are observed and may complicate proper interpretation of local phases on the basis of an oversimplified travel-time model as the one in Fig. 2.48. Then special modelling may be required, which is beyond the scope of seismic routine analysis. According to Bock et al. (1996) these strong onsets (?) may be related to local depth phases (e.g., sPmP in Fig. 2.49).

**Fig. 2.49** Two records of a local earthquake at a source depth of  $h = 6$  km in eastern Germany. The strong seismic phase ? between the onsets of Pg and Sg at hypocenter distance of 122 km in the record of station BRG can not be identified by using the simplified set of travel-time curves for surface foci in Fig. 2.48. According to model calculations it is most likely the depth phase sPmP of the large amplitude overcritical reflection PmP from the Moho discontinuity.

Also be aware that in the case of sub-crustal earthquakes, which are common in subduction zones, none of the crustal phases discussed above exist. In this case, the first arriving longitudinal and shear wave onsets are usually termed P and S, respectively, as for teleseismic events (see Fig. 2.50) although the IASPEI standard phase nomenclature terms them also Pn and Sn for upgoing rays from the source that are recorded in the local distance (see Figure 1c in IS 2.1; Storchak et al. 2003 and 2011).

**Fig. 2.50** P- and S-wave onsets from a local earthquake in northern Chile at a depth of 110 km and a hypocenter distance of about 240 km (courtesy of B. Schnurr, 2001).

## 2.6.2 Shallow source body-waves and travel times at teleseismic distances

Seismic waves arriving at distances beyond  $10^\circ$  up to about  $30^\circ$  have mainly traveled through the upper mantle (from Moho to about 410 km depth) and the transition zone to the lower mantle (between about 410 km and 660 km depth). The strong discontinuities which mark the upper and lower boundary of the transition zone are associated with strong increases in seismic impedance (i.e., of both velocity and density; see Fig. 2.7). This results in two remarkable triplications of the travel-time curve for P waves (see Fig. 2.32) and S waves, which give rise to complicated waveforms of rather long duration (about 10 s and more) and consisting of a sequence of successive onsets with different amplitudes (Fig. 2.51).

**Fig. 2.51** Broadband seismograms with high time resolution showing the complex P-wave groups in records of an earthquake in southern Turkey at stations of the German Regional Seismograph Network (GRSN) at epicenter distances between  $D = 19.7^\circ$  (GEC2) and  $24.8^\circ$  (GSH).

For epicenter distances  $D > 30^\circ$  P and S waves are followed by an increasing number of secondary waves, mainly phases, which have been reflected or converted at the surface of the Earth or at the core-mantle boundary(CMB). Fig. 2.52 depicts a typical collection of possible primary and secondary ray paths together with a three-component seismic record at a distance of  $D = 112.5^\circ$  that relates to the suit of seismic rays shown in red in the upper part of the cross section through the Earth. The phase names are standardized and in detail explained in IS 2.1

**Fig. 2.52 Top:** Seismic ray paths through the mantle (**M**), outer core (**OC**) and inner core (**IC**) of the Earth (above) with the respective phase symbols according to the international nomenclature (see IS 2.1, also for detailed ray tracing). Full lines: P rays; broken lines: S rays. Related travel-time curves are given in Fig. 2.60. Red rays relate to the seismic phases identified in the 3-component Kirnos SKD broadband seismogram recorded at station MOX, Germany (**bottom**) of body-waves from an earthquake at an epicenter distance of  $112.5^\circ$ .

Between about  $30^\circ$  and  $100^\circ$  epicenter distance P and S have traveled through the lower mantle, which is characterized by a rather smooth positive velocity and density gradient (see Fig. 2.79). In this distance range, seismograms are relatively clearly structured with P and S (or beyond  $80^\circ$  with SKS) being the first, prominent longitudinal and transverse wave arrivals, respectively, followed by multiple surface and core-mantle boundary (CMB) reflections or conversions of P and S such as PP, PS, SS and PcP, ScP etc. (see travel-time curves in Fig. 2.60).

Within about 15 to 35 min after the first P arrival multiple reflections of PKP from the inner side of the CMB (PKKP; P3KP) or from the surface (PKPPKP = P'P') may be recognizable in short-period seismic records. Their travel-time curves have been plotted in the left-hand panel and their ray traces in the right-hand panel of Fig. 2.53. Many more of such multiple core phase records are presented in Chapter 11, section 11.5.3.

**Fig. 2.53 Left:** Short-period teleseismic travel-time curves and **right:** ray paths of PKKP and P'P' (= PKPPKP) with respect to the direct P phase (courtesy of S. Wendt, 2001).

Beyond  $100^\circ$ , P-wave rays, which entered the outer core after strong downward refraction, will return with time delay to the surface as PKP core phases (Fig. 2.53 left). This is due to the strong reduction of the P-wave velocity at the CMB from about 13.7 km/s in the lowermost mantle to 8.0 km/s in the upper outer core. Thus, short-period P waves form a *core shadow* whereas PKP forms a caustic around  $145^\circ$  due to the slow velocity increase in the liquid outer core and the strong positive velocity gradient in the transition to the solid inner core (see 2.76). This results in strong amplitudes that are comparable with those of P at much shorter distances around  $50^\circ$  (see Chapter 3, Fig. 3.34). At the caustic of PKP three different branches of PKP meet (see Figs. 2.53 and 2.54 and Chapter 11, Figs. 11.72 and 11.73).

**Fig. 2.54** Short-period (left) and long-period (right) seismograms for the Mid-Indian Rise earthquake on May 16, 1985 ( $M = 6.0$ ,  $h = 10$  km) in the range  $D = 145.6^\circ$  to  $173.2^\circ$ . (From Kulháněk (1990), *Anatomy of Seismograms*, plate 55, pp. 165-166, © with permission from Elsevier Science). Note: The figure above gives still the old names of the core phases. According to the new IASPEI phase names PKP2 should be replaced by PKPab, PKP1 by PKPbc and PKIKP by PKPdf (see IS 2.1, also for the detailed ray tracing of these phases).

Note, however, that long-period P-wave energy is diffracted around the CMB into this shadow zone for short-period P-wave energy up to about  $150^\circ$  (Fig. 2.55). According to the new IASPEI nomenclature of phase names (see IS 2.1) the diffracted P wave is termed Pdif, however the old phase symbol Pdiff is still widely used. The amplitudes of Pdif are much smaller than those of PP, which is the strongest longitudinal arrival in the far teleseismic range (see Fig. 2.55 and Figs. 11.74 and 11.75 in Chapter 11).

In more detail, the types of seismic phases appearing at teleseismic distances and their peculiarities are discussed in Chapter 11, where many additional record examples are given, complemented by Datasheets DS 11.2 and 11.3.

**Fig. 2.55** Long-period records of Pdif, PKPdf (with shortly after following PKPbc between 145° and 157° and PKPab (between 145 and 180°; all better discernable in the short-period records of Fig. 2.54), and PP (courtesy of S. Wendt, 2002).

The first discernable motion of a seismic phase in the record is called the *arrival time* and the measurement of it is termed *picking* of the arrival (see Chapter 11, section 11.2.2). Up to now, arrival time picking and reporting to international data centers is one of the major operations of data analysts or automatic analysis systems at seismic stations or network centers. By plotting the time differences between reported arrival times and calculated origin times over the epicenter distance, seismologists were able to construct travel-time curves for the major phases and to use them to infer the average radial velocity structure of the Earth (see 2.7).

In Fig. 2.56 (left) more than five million travel-time picks, archived by the International Seismological Centre (ISC) for the time 1964 to 1987, have been plotted. Most time picks align nicely to travel-time curves, which match well with the travel-time curves theoretically calculated for major seismic phases on the basis of the IASP91 model (Fig. 2.56 right).

**Fig. 2.56 Left:** Travel-time picks collected by the ISC between 1964 and 1987 for events shallower than 50 km. (From Shearer, *Introduction to Seismology*, 1999; © with permission from Cambridge University Press). **Right:** IASP91 travel-time curves for surface focus (from Kennett, 1991).

An even more complete picture of the entire seismic wavefield may nowadays be obtained by stacking data from global digital seismic networks. Records at common source-receiver ranges have been averaged to produce a composite seismogram. Stacks of almost 100,000 seismograms from the global digital networks have been plotted by Astiz et al. (1996; Fig. 2.57 for short-period records with periods  $T < 2$  s and Fig. 2.58 for long-period records with  $T > 10$  s). Although the arrivals appear sharper at higher frequencies and late arriving reflected core phases P'P' (PKPPKP), PKKP as well as higher multiples of them are discernable in short-period records only, in total much less later phases can be distinguished in short-period records. The darker the dot “curves” appear against the gray background the larger is the relative frequency with which these phases can be observed above the noise level. Figs. 2.59 and 2.60 present the calculated travel-time curves for the IASP91 velocity model (Kennett and Engdahl, 1991) together with the phase nomenclature. The theoretical travel-time curves match excellent with the difference between automatically picked onset times and origin time.

**Fig. 2.57** Stack of short-period filtered ( $T < 2$  s), vertical component data from the global networks between 1988 and 1994 (from Astiz et al., Global Stacking of Broadband Seismograms, *Seismological Research Letters*, Vol. 67, No. 4, p. 12, © 1996; with permission of Seismological Society of America).

**Fig. 2.58** Stack of long-period ( $T > 10$  s), vertical component data from the global networks between 1988 and 1994. (from Astiz et al., Global Stacking of Broadband Seismograms, *Seismological Research Letters*, Vol. 67, No. 4, p. 14, © 1996; with permission of Seismological Society of America).

**Fig. 2.59** Overlay to Fig. 2.57 with the theoretical IASP91 travel-time curves for surface foci and the related phase nomenclature. Produce a 1:1 copy on a transparent sheet and match it with Fig. 2.57.

**Fig. 2.60** Overlay to Fig. 2.58 with the theoretical IASP91 travel-time curves for surface foci and the related phase nomenclature. Produce a 1:1 copy on a transparent sheet and match it with Fig. 2.58.

Complementary to Figs. 2.57 and 2.58, Fig. 2.61 reveals the different polarization of the various seismic phases.

**Fig. 2.61** Global travel-time curves for shallow earthquakes as produced by stacking broadband seismograms. Seismic phases are shown in different colors depending on their polarization (**blue**: vertical motion; **green**: radial-horizontal; and **red**: transverse-horizontal) (courtesy of L. Astiz).

While all primary longitudinal phases and all from P or K to S converted phases, and vice versa, appear on vertical and radial-horizontal components only, multiple reflected S waves, which lose with each reflection more and more of their SV polarized energy due to conversion into P (or K at the CMB), become more and more transversely polarized. Primary

S, however, has significant energy on both horizontal components that are oriented either parallel to the backazimuth to the source (radial) or perpendicular to it (transverse). Direct P waves, polarized in the direction of ray propagation, have in the teleseismic range dominating vertical components because of their steep incidence angle, which gets smaller and smaller with increasing distance (see e.g., PKP phases). PP, P3 and higher multiples may, however, have significant energy in the radial component too. These examples illustrate that the visibility and discrimination of body wave phases in seismic records depends on their relative amplitude, polarization and frequency content. All of these criteria have to be taken into account, besides the differences in travel-times, when analyzing seismic records.

### 2.6.3 Depth phases

In the case of distant deep earthquakes the direct P wave that leaves the source downward will arrive at a teleseismic station first. It will be followed, depending on the source depth, up to about 4.5 min later, by other phases that have left the source upward (Fig. 2.62). These phases, also when associated with PP, S, SS and reflected or converted at the free surface of the Earth or at the ocean bottom (such as pP, sP, ' , sPP, pPKP, etc.), at the free surface of the ocean (e.g., pwP, swP), or from the inner side of the Moho (e.g., pm-P) are called *depth phases*. Their proper identification, onset-time picking and reporting is of crucial importance for reliable determination of source depth (see below and section 6.1 with Figure 7 in the Information Sheet IS 11.1). Differential travel-time tables for pP-P and sP-P are presented in Exercise EX 11.2. For the definition of these phases see also IS 2.1.

**Fig. 2.62 Left:** Different ray paths of a direct teleseismic P wave and of its depth phases. **Right:** Records of depth phases of the May 24, 1991 Peru earthquake (hypocenter depth  $h = 127$  km); a) broadband record and b) simulated short-period recording (the right figure is a corrected cutout of Fig. 6.4 of Lay and Wallace, *Modern Global Seismology*, p. 205, © 1995; with permission of Elsevier Science, USA).

Depth phases of P, PP, S, SS or of converted P or S phases have commonly smaller amplitudes because of reflection and/or conversion losses as well as extra attenuation along the additional segment of travel. For shallow earthquakes a clear discrimination between

direct and depth phases is difficult and usually beyond the possibilities of routine seismogram analysis because of the closeness in time of the subsequent phase onsets and the superposition of their waveforms. They may, however, be discriminated by waveform modeling and matching for variable source depth and source mechanism (see subchapter 2.8, Fig. 2.85). Yet, in any event, for shallow earthquakes, short-period seismic records that emphasize on periods  $< 2\text{--}3\text{ s}$  are more suitable for identifying and time-picking of closely spaced depth phase onsets than broadband displacement or (somewhat better) velocity records (Fig. 2.63).

**Fig. 2.63** Appearance of P, pP and sP in displacement (DIS) and velocity (VEL) broadband as well as short-period vertical component records. The source depths of the earthquakes have been 18 km (left) and 40 km (right), respectively. Copied from Figures 1 and 5 in Choy and Engdahl (1987), *Phys. Earth Planet. Int.* **47** (© Elsevier Science Publ., 2012).

Yet, depth phases may sometimes also be larger than their primary phases, as confirmed by both observations (e.g., Fig. 2.62 upper right, Fig. 2.63 right and 2.64 below) and synthetic modeling (e.g., Langston and Helmberger, 1975).

**Fig. 2.64** Medium-period displacement-proportional record of P, PP and their depth phases by a Kirnos SKD seismograph ( $T_s = 20\text{ s}$ ;  $T_g = 1.25\text{ s}$ ;  $V_{\max} = 1000$  times) at station MOX, Germany, of an earthquake in the Afghanistan-USSR border region on 06 June 1966 ( $D = 44.3^\circ$ ,  $h = 220\text{ km}$ ). Copy of Fig. 7 in Bormann (1969).

The great variability of amplitudes of both P and PP (also S and SS) and of their depth phases is a source-mechanism dependent function of take-off angle and azimuth and thus varies with distance and azimuth of the recording station in respect to the source radiation pattern.

Although the inclusion of correctly identified depth phases into the location procedure (besides S, PKiKP, PKPdf, PcP, ScP, if available) may significantly improve hypocenter location their proper identification becomes even more difficult if the reflection/conversion points of the up-going p or s rays are underneath an ocean with significant water depth. In this case significant reflection/conversion may occur both at the ocean bottom and at the ocean surface. While the former would be the common pP or sP phase, the latter requires a specifying phase name, namely pwP or swP (w = water). There maybe even double reflections within the water column, making, e.g., for a pwwP (see Fig. 2.65).

**Fig. 2.65 Top:** Average crust-ocean layer velocity model with seismic rays of P and its depth phases (amended after Mendiguren, 1971). **Bottom:** A short-period record example of these phases according to Engdahl and Billington (1986).

These ocean depth phases have first been described by Mendiguren (1971) and later in more detail by Yoshiu (1979) and Engdahl and Billington (1986). Since the water layer depth phases follow the primary depth phases usually within about 10-15 s, their waveforms are better discernable and their onset times more reliable to pick on short-period or velocity broadband records than on long-period or displacement broadband records (Fig. 2.66).

**Fig. 2.66** P and the depth-phase reflections from the oceanic sediment-basement interface ([pP] and [sP]), from the sediment-water interface (pP and sP), from the water surface (pwP and swP), as well as the multiples of the latter, once again reflected within the water layer (pwwP and swwP) (see Fig. 2.65 top), recorded with different instruments. Vertical bars mark the model-dependent theoretically calculated onset times of these phases. The figure was modified for better time-resolution from Figure 3b in Engdahl and Kind (1986), *Annales Geophysicae*, 4, (© European Geophysical Society, 2012).

According to the record examples shown, the water-layer depth phases may be even larger than the primary depth phases. Misinterpretations are therefore rather common. About one-third of the ISC identifications as pP, sP and PcP have been re-identified in a special analysis carried out by Engdahl et al. (1998). According to these authors quite many ISC pP, sP and partially also PcP phases have in fact been pwP and many sP onsets had been misinterpreted as pP. If a pwP phase produced by a water layer 4 km thick is misinterpreted as pP this may result (in the absence of local or regional P phases) in an overestimation of the focal depth by about 50 km. Therefore, Engdahl et al. (1998) developed an automatic phase identification algorithm, termed EHB for short, which aims at significantly improved hypocenter relocations. EHB is applied to the phase group which immediately follows the P phase at teleseismic distances, including pP, pwP, sP and PcP and allows the unambiguous identification of later phases such as S. In conjunction with there publication the authors relocated some 100.000 earthquakes. The EHB bulletin is now permanently updated and complemented and posted on the ISC website <http://www.isc.ac.uk/>.

#### 2.6.4 $P_z \pm P$ , $S_z \pm S$ , $P_z \pm S$ , $S_z \pm P$ , etc.

Since the *impedance contrasts* at the free Earth surface, the ocean bottom and the core-mantle boundary are larger than at any other velocity-density discontinuity in the Earth, reflected and converted P and S phases from these discontinuities dominate the secondary body-wave onsets in seismograms. None the less, there are several other globally represented

discontinuities of significant contrast which give rise to additional reflections and conversions of P and S phases which may appear even in unprocessed seismograms as recognizable fore- or after-runner onsets to the primary phases P and S and thus complicate for analysts the proper phase identification and onset picking. The most important discontinuities in this regard are the Moho as well as the discontinuities bordering the upper mantle transition zone at about 410 km and 660 km depth. According to IS 2.1 as well as Storchak et al. (2003 and 2011) the unified nomenclature for such phases is:

- **Pz+P or Sz+S:** P or reflection from the **outer** (top) side of a discontinuity at depth  $z$  outside of the core;  $z$  may be a positive numerical value in km, e.g., P660+P or S660+S, which are then reflections of P or S from the top of the 660 km discontinuity, or  $z$  may be a letter, e.g., m for Moho (see Pm+P and the bottom side reflection pm-P in Fig. 2.67).

**Fig. 2.67 Left:** Travel-time curves and records of critically reflected crustal P and S waves from the upper side of the Moho: Pm+P and Sm+S, respectively. **Note:** The +sign is not obligatory to identify the phase as on upward reflection from the upper side of a discontinuity. Writing PmP and SmS instead is acceptable. See IS 2.1. Modified from Fig. 2.47;

**Right:** Depth phase pP from an earthquake at the Tyrrhenian Sea (13.04.1938,  $h = 256$  km) recorded at the station Sverdlovsk, Russia ( $D=33^\circ$ ), together with its smaller forerunner phase pm-P which is the downward reflection of the upcoming ray p on the inner (bottom) side of the Moho (see next bullet point). Modified Figure 108 in Savarenski and Kirnos (1960).

- **Pz-P or Sz-S:** P or S reflection from the **inner** (bottom) side of a discontinuity at depth  $z$  outside of the core, e.g., at the Moho (see Fig. 2.67 right) or in the Earth upper mantle such as P660-P or S410-S which are the P or S reflections from below the 660 km and 410 km discontinuity, respectively, and **precursory to PP or SS** (Fig. 2.68 and 2.69). **Note:** Writing the -sign is in these cases obligatory to identify them as a downward reflections from the bottom side of the discontinuity.

**Fig. 2.68** Aligned long-period records of SS phases (very large amplitudes on the outermost right) and of their much weaker precursors reflected from the inner (bottom) side of the discontinuities in the mantle at 410 km (**S410-S**) and 660 km (**S660-S**) depth from different earthquakes recorded at different seismic stations and distances: Trace 1: 1983 Oct 17 19:36:21.5 ; Trace 2: 1980 Jan 27 16:38:01.1; Trace 3: 1988 Feb 06 18:03:54.8; Trace 4: 1980 Oct 25 11:00:05.1; Trace 5: 1990 Feb 19 05:34:37.4; Trace 6: 1990 Dec 17 11:00:19.6; Trace 7: 1989 Apr 18 12:33:54.8; Trace 8: 1984 May 26 22:42:47.3; Trace 9: 1989 Dec 03 14:16:48.8; Trace 10: 1986 Jun 28 05:03:47.5. The vertical bars mark the theoretical travel times with respect to S410-S according to the global IASP91 model. Modified after Gossler and Kind (1996).

**Fig. 2.69 Left:** Similar to Fig. 2.68 but stacked and color-coded record section in a wide distance range, and aligned with respect to the arrival time of the free surface reflection of SS. Clearly visible are the fainter precursory arrivals of S660-S and S410-S, which arrive about 4 and 2.5 min ahead of the SS. **Right:** The same for the still weaker P410-P with respect to PP. Modified from Figure 1 in Shearer and Flanagan (1999), *Science*, **285**, p. 1546, in order to agree with IASPEI standard phase nomenclature (© Science).

- Accordingly,  $P_z+S$  and  $S_z+P$  or  $P_z-S$  and  $S_z-P$ , respectively, are P or S waves that have been converted into S or P when reflected from the outer (top) or inner (bottom) side, respectively, of a discontinuity at depth  $z$ .
- In an analog way the above notations apply also to  $PKP = P^I$  and  $SKS = S^I$  phases, such as  $P^I_z-P^I$  being a PKP phase reflected from the inner (top) side of a discontinuity at depth  $z$  outside the core, thus being precursory to  $P^I = PKP$ . A fine example is given in Fig. 2.70.

Usually, however, the SNR of such phases is too small to be recognized and picked correctly in routine seismogram analysis.

**Fig. 2.70**  $P^I P^I$  record section for a South American earthquake recorded by the California seismic array showing weak but distinct precursors  $P^I P^I$  and  $P^I P^I$ . Modified from Fig. 2a of Benz and Vidale (1993), *Nature*, **365**, p. 148, in order to agree with IASPEI standard phase nomenclature. (© Copyright Clearing Centre of Nature).

### 2.6.5 T phases

The letter *T* stands for *Tertiary wave*. This term has been introduced into seismology by Linehan (1940) in order to discriminate these waves from the much earlier arriving P (primary) and S (secondary) waves radiated by the seismic source that have travelled all their way through the Earth. T waves are generated by earthquakes, explosions or volcanic eruptions in or near the oceans, propagate in the oceans as an acoustic wave guided in the

*SOFAR channel* (Bullen and Bolt, 1985) or by multiple reflections between the sea floor and the sea surface (Båth and Shahidi, 1974) and are converted back to seismic waves at the ocean-land boundary near the recording site. The SOFAR channel is a depth range of low acoustic velocity within the ocean water column which “traps” sound waves to propagate over very large distances with very low attenuation. Thus it is a very efficient *wave guide* for the seismic *T phase*. T waves are generally short-period waves because they can propagate efficiently only, if their wavelengths fit inside the width of the SOFAR channel. This is the case for frequencies above 2 Hz only (see Okal et al., 2003, and records in Figs. 2.71 and 2.72). T waves are best recorded by ocean-bottom seismometers (OBS) and hydrophone stations (see Chapter 7, section 7.5) and by near coastal inland stations. Typical for T phases is their gradual increase and subsequent decrease of the amplitudes of rather monochromatic oscillations with a total duration up to several minutes and hardly any recognizable onset time (see the markers ET set in Fig. 2.71).

Since T phases travel through the SOFAR channel with much lower velocity than the direct P and S waves radiated by the seismic source, the T phases arrive much later in the seismic record, the later the longer the SOFAR path. Therefore, they may be misinterpreted as independent seismic events. Figs. 2.71 and 2.72 present T-phase records at stations of the Norwegian National Seismic Network from two earthquakes in the Atlantic Ocean.

**Fig. 2.71** High-frequency filtered records (passband 5 to 10 Hz) at stations LOF, TRO, MOR8 and KTK1 in Norway of the shallow ( $h = 5$  km)  $M_l = 5.2$  Mohns Ridge earthquake on 20 Aug. 2009. Note the at least some 2 minutes long gradual T phase with no clearly recognizable onset ET which follows about 4 to 5 min after the first P onset. The epicenter distance of the stations and their distance from the coast (second number in brackets) are – from top to bottom - for LOF 730 km (15 km), TRO 710 km (30 km), MOR8 860 km (100 km) and KTK1 900 km (200 km). (Modified version of an original record plot kindly provided by Lars Ottemöller, 2011).

Although the amplitudes of the primary and secondary earthquake waves in all 4 records are about the same, the T-phase amplitudes decrease strongly with increasing distance from the coast due to the rather strong attenuation of the high-frequency waves travelling through the rather heterogeneous uppermost crust. This, however, is not a strict rule, obviously modified by differences in the efficiency of the conversion of the acoustic SOFAR channel waves into seismic waves at the coastal bounce point as well as differences in the attenuation conditions along the travel paths on land. In the second record example in Fig. 2.72, e.g., the T-phase amplitudes recorded on station KTK1 at a coastal distance of 220 km are larger than those recorded on stations TRO and HAMF at 30 km and 75 km coastal distance, respectively.

**Fig. 2.72** High-frequency filtered records (passband 5 to 10 Hz) at stations HAMF, KTK1, LOF, and TRO in Norway of the shallow ( $h = 10$  km)  $M_l = 6.1$  Jan Mayen region earthquake on 29 Jan. 2011. Note the up to about 4 min long T phase which follow about 6 to 8 min after the first P onset. The epicenter distance of the stations and their distance from the coast (second number in brackets) are – from top to bottom – for HAMF 1115 km (75 km), KTK1 1165 km (220 km), LOF 845 km (15 km), TRO 970 km (30 km). (Modified version of an original record plot kindly provided by Lars Ottemöller, 2011).

As compared to ordinary sub-marine and *tsunamigenic earthquakes*, high-frequency T waves are highly deficient (by 1.5 to 2.5 orders of magnitude) in records of very slow rupturing *tsunami earthquakes*. Therefore, Okal et al. (2003) suggested that computations of T-phase efficiency might become a valuable contribution to real-time tsunami warning in the far field.

## 2.6.6 Surface-wave fundamental and higher modes and the W phase

The basic types of horizontally propagating seismic surface waves (Rayleigh waves, Love waves, and their higher modes; see 2.3 in Chapter 2) remain more or less unchanged with growing distance. Surface waves, however, do not form seismic phases (wavelets) with well-

defined onsets and duration but rather dispersed wave trains (see Figs. 2.12, 2.13, 2.20). Due to the dispersion their duration increases with distance. Although it is very common to determine the magnitude of shallow seismic events by means of surface waves ( $M_{s\_20}$  and  $M_{s\_BB}$ ; see Chapter 3 and IS 3.3), the analysis of surface-wave group and phase velocities for investigating Earth structure and properties requires specific methods of analysis and is beyond the scope of seismological observatory practice. Moreover, the phenomenology of seismic surface-wave trains is sometimes complicated by near surface heterogeneities. E.g., surface wave trains of relatively high frequencies, as generated by shallow local events, may additionally be prolonged significantly due to lateral reverberations when propagating through strong lateral velocity contrasts in the crust (see Fig. 2.73). This phenomenon was used by Meier et al. (1997) to establish a tomography with reflected surface waves.

**Fig. 2.73** Ray paths of surface waves (broken lines) from a mining collapse (star) to several seismic stations in the eastern part of Germany. Note: Records at stations along travel paths that have not or only once crossed some of the main tectonic faults in the area, are rather short. They have only one surface-wave maximum. In contrast, at station PRW, which is at the same epicenter distance as HAL, the seismic record is about four times longer and shows four surface-wave groups due to multiple reflections at several pronounced fault systems (compiled from data provided by H. Neunhöfer (1985; and personal communication)).

Recently, the analysis of the long-period *W phase*, which arrives before the onset of *S* (Fig. 2.74), has gained immense practical importance for speeding up seismic tsunami warning. Kanamori (1993) has been first to name and extensively document this phase. According to Kanamori and Rivera (2008) the *W phase* can be interpreted as superposition of the fundamental, first, second and third overtones of spheroidal modes or Rayleigh waves. Its group velocity varies between 4.5 and 9 km/s over a period range of 100 to 1000 s. The amplitudes of so long-period waves represent well the tsunami potential of great earthquakes. *W phase* inversion may yield reliable and non-saturating estimates of seismic moment and moment magnitude as well as of the source mechanism of large earthquakes within about 20 minutes of the earthquake occurrence (Fig. 2.75). Source inversion of the *W phase* has

recently been extended down to approximately  $M_w$  6. Real-time implementations are operational at the U.S. Geological Survey's NEIC (Hayes et al., 2009) as well as at the GFZ Potsdam and the Indonesian Tsunami Early Warning System (InaTEWS).

**Fig. 2.74** W phase record of the 2001  $M_w8.4$  Peruvian earthquake at HRV superimposed with the synthetic W phase trace (red) computed by mode summation using the Global Centroid Moment Tensor solution for this earthquake (copy of Figure 1 on page 223 of Kanamori and Rivera, 2008; © Geophysical Journal International).

## 2.7 Global Earth models (E. R. Engdahl)

### 2.7.1 1-D models

In the first part of the 20th century travel-time models for seismic phases, empirically derived from historical data, were rudimentary at best. One of the earliest travel-time model, the Zoeppritz tables (Zoeppritz, 1907) were applied by Herbert Hall Turner in a version as published by Galitzin (1914) to locate earthquakes for the ‘Bulletin of the British Association of the Advancement of Science, Seismology Committee’ for the years 1914 until 1917. During the 1920s, Turner gradually expanded these tables for newly discovered phases and better phase observations, often suggested and derived by Beno Gutenberg. These Zoeppritz-Turner tables were in use to locate earthquakes for the International Seismological Summary (ISS) from 1918 to 1929. This situation greatly improved with the introduction of the Jeffreys-Bullen (J-B) tables (Jeffreys and Bullen, 1940), which provided a complete, remarkably accurate representation of P, S and other later-arriving phases. Like the Gutenberg-Richter travel-time tables, the J-B tables were developed in the 1930s using reported arrival times of seismic phases from a sparse global network of stations, many of which often had poor time-keeping. Once the travel times of the main phases had been compiled, smoothed empirical representations of these travel times were inverted using the Herglotz-Wiechert method to generate a velocity model. The travel times for other phases were then determined directly from the velocity model. As a testament to the careful work that went into producing the J-B tables, they were until only recently used by the International Seismological Centre (ISC) and by the U. S. Geological Survey National Earthquake Information Center (NEIC) for routine earthquake location. Both agencies now use the AK135 tables.

Although the limitations of the J-B tables were known for some time, it was not until the early 1980’s that a new generation of models was constructed in a completely different way. Instead of establishing smoothed, empirical representations of phase-travel times, inverse modeling was used to construct one-dimensional models for structure that fit phase travel times reported in the ISC Bulletin since 1964 and other parametric data. The Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981) was the most important member of this generation of new global 1-D models. However, PREM was constructed to fit both body-wave travel-time and normal-mode data, so it was not generally thought to be especially useful for earthquake location. In fact, soon afterwards Dziewonski and Anderson (1983) published a separate analysis of just P waves in an effort to produce an improved travel-time table.

In 1987 the International Association of Seismology and Physics of the Earth’s Interior (IASPEI) initiated a major international effort to construct new global travel-time tables for earthquake location and phase identification. As a result of this effort two models were developed: IASP91 (Kennett and Engdahl, 1991); and SP6 (Morelli and Dziewonski, 1992). Although differences in predicted travel times between these two models were small, some effort was still required to reconcile the travel times of some important, well-observed seismic phases before either of these models could be used by the ISC and NEIC for routine earthquake location. The upper mantle part of the IASP91 model was fitted to summary P and S wave travel-times, binned in 1° intervals of epicenter distance, published by Dziewonski and Anderson (1981, 1983) (Fig. 2.76).

**Fig. 2.76** Fitting of IASP91 upper mantle travel times as a function of epicenter distance to the summary first-arrival travel times of P (top) and S waves (bottom) according to Dziewonski and Anderson (1981, 1983) in time-reduced presentation (from Kennett and Engdahl, 1991).

As shown in Fig. 2.77, the IASP91 upper mantle differed substantially from PREM and, in particular, IASP91 had no mantle low-velocity zone for either P or S waves. Although this did run counter to the prevailing ideas about upper mantle structure, it did have a practical advantage for locating events because the upper mantle travel times in IASP91 were not discontinuous. Characteristics of the main upper mantle discontinuities were also different from previous models. In IASP91 the 210 km discontinuity was essentially absent. The 410 km and 660 km discontinuity velocity jumps in IASP91 were slightly greater in amplitude than in PREM. Path coverage was generally more uniform in the lower mantle, so these parts of the IASP91 P and S models were considered to be more representative of the average

Earth. P structure was reasonably well constrained, except near the core-mantle boundary, but the complication of interfering phases put a practical limit on the amount and quality of data constraining S structure. Nevertheless, IASP91 seems to have done a reasonably good job of representing teleseismic travel times, as indicated by the analysis of arrival-time data from well-constrained explosions and earthquakes (Kennett and Engdahl, 1991).

**Fig. 2.77** Comparison of upper mantle velocity models for IASP91, PEMCA, and PREM (from Kennett and Engdahl, 1991). Left:  $\beta$  - speed of S wave; right:  $\alpha$  - speed of P wave.

Morelli and Dziewonski (1993) developed an alternative model (SP6) using the same model parameterization and upper mantle model as Kennett and Engdahl (1991). In their approach, they solved for multiple source-region station corrections averaged over  $5^\circ$  areas to account for lateral heterogeneity in an approximate manner. They then derived new sets of summary travel times for lower mantle and core P and S phases binned in  $1^\circ$  intervals of epicenter distance, and inverted those summary times for 1-D P and S velocity models. Although lower mantle P and S in the resulting model was generally comparable to IASP91, the models differed in that SP6 had slightly lower velocity gradients with depth and correspondingly higher velocity jumps at the 660-km discontinuity. Moreover, SP6 had incorporated a pronounced negative velocity gradient in the D'' region, a layer 100-150 km thick just above the core-mantle boundary. The SP6 model fitted the S data and all core-phase observations significantly better than IASP91. The differences in the seismic velocities between the models were significant for the core, owing to the addition of substantial core phase data in the construction of SP6.

The most significant differences between these new models and the older J-B travel-time model are in the upper mantle and core. The upper mantle is highly heterogeneous. Hence, velocities and major discontinuities in the upper mantle of recent models such as IASP91 and SP6 are set at values, which give an effective average representation of velocities for waves

traveling out to  $25^\circ$  (see Kennett and Engdahl, 1991). The core models for IASP91 and SP6 predict more accurately than the J-B model the observed travel times of later-arriving core phases bottoming in the lowermost part of the outer core.

These models also resolve a long-standing problem in that the relocation of nuclear tests using the J-B travel-time model results in incorrect estimates of the origin times of nuclear explosions by about -1.8 sec. This error will propagate into all derived travel times and may affect the procedure of phase association. Kennett and Engdahl (1991) resolved this error in the absolute travel time (or "baseline" error) by fitting the IASP91 model to the mean teleseismic residual estimated from the origin times and hypocenters reported for explosions and well-constrained earthquakes by "test event" contributors. As a result, the times of teleseismic P and S waves for the IASP91 model now appear to be in better agreement with the travel time data than the times predicted by the J-B model. The IASP91 model has been adopted as the global reference model for the International Data Centre in Vienna established under the 1996 Comprehensive Nuclear-Test-Ban Treaty (CTBT).

Subsequently, Kennett et al. (1995) began with the best characteristics of the IASP91 and SP6 models and sought to enhance the data quality by improving the locations of a carefully selected set of geographically well-distributed events. The basic strategy was to use a location algorithm developed by Engdahl et al. (1998) with a IASP91 model modified to conform to the SP6 core to relocate events and improve phase identifications using only first arriving P phases and re-identified depth phases (pP, pwP and sP). The resulting set of smoothed empirical relations between travel time and epicenter distance for a wide range of re-identified seismic phases was then used to construct an improved reference model for the P and S radial velocity profile of the Earth (AK135). A composite residual plot (Fig. 2.78) shows that the model AK135 provides a very good fit to the empirical times of 18 seismic phases. The baseline and trend of S is well presented and most core phase times are quite well matched. Thus, for improved global earthquake location and phase association, there has been convergence on effective global, radially symmetric P- and S-velocity Earth models that provide a good average fit to smoothed empirical travel times of seismic phases.

The primary means of computing travel times from such models is based on a set of algorithms (Buland and Chapman, 1983) that provide rapid calculation of the travel times and derivatives of an arbitrary set of phases for a specified source depth and epicenter distance. In the mantle, AK135 differs from IASP91 only in the velocity gradient for the D" layer and in the baseline for S wave travel times (about -0.5 sec). Significant improvement in core velocities relative to earlier model fits was also realized. Inner core anisotropy, as discussed in the literature, is not yet accounted for in any of the newer 1-D Earth models. However there are so few reported arrivals of PKPdf at large distances along the spin axis of the Earth that the effects of this anisotropy in earthquake location are negligible.

The model AK135 has since been used for further reprocessing of the arrival time information (Engdahl et al., 1998). The reprocessed data set and the AK135 reference model have formed the basis of much recent work on high-resolution travel-time tomography to determine three-dimensional variations in seismic wave speed (e.g., Bijwaard et al., 1998). However, it is important to recognize that none of these models can properly account for the effect of lateral heterogeneities in the Earth on teleseismic earthquake location. Most deeper than normal earthquakes occur in or near subducted lithosphere where aspherical variations in seismic wave velocities are large (i.e., on the order of 5-10%). Such lateral variations in seismic velocity, the uneven spatial distribution of seismological stations, and the specific choice of

seismic data used to determine the earthquake hypocenter can easily combine to produce bias in teleseismic earthquake locations of up to several tens of kilometers (Engdahl et al., 1998). For a review of recent advances in teleseismic event location, with the primary emphasis on applications using one-dimensional velocity models such as AK135, the reader is referred to Thurber and Engdahl (2000). The most accurate earthquake locations are best determined using a regional velocity model with phase arrival times from a dense local network, which may differ significantly (especially in focal depth) from the corresponding teleseismic locations.

**Fig. 2.78** Composite display of the estimates of standard deviations for the empirical travel times used in the construction of the AK135 velocity model (Kennett et al., 1995).

The AK135 wave speed reference model is shown in Fig. 2.79. However, though the P- and S-wave speeds are well constrained by high-frequency seismic phases, more information is needed to provide a full model for the structure of the Earth.

**Fig. 2.79** Radial symmetric reference models of the Earth. **Top:** AK135 (seismic wave speeds according to Kennett et al., 1995), attenuation parameters and density according to Montagner and Kennett (1996); **Bottom:** PREM (Dziewonski and Anderson, 1981).  $\alpha$  - and  $\beta$ : P- and S-wave velocity, respectively;  $\rho$  - density,  $Q_\alpha$  and  $Q_\beta = Q_\mu$  - “quality factor”  $Q$  for P and S waves. Note that wave attenuation is proportional to  $1/Q$ . The abbreviations on the outermost right stand, within the marked depth ranges, for: C – crust, UM – upper mantle, TZ – transition zone, LM – lower mantle, D''-layer, OC – outer core, IC – inner core.

In particular, any reference model should also include the density and inelastic attenuation distributions in the Earth. Work by Montagner and Kennett (1996) provided these parameters which, although known less precisely than the seismic velocities, are needed because it makes the model suitable for use as a reference to compute synthetic seismograms (see 2.8) without requiring additional assumptions. Nevertheless, the primary use of AK135 (and IASP91) remains earthquake location and phase identification. The PREM model of Dziewonski and Anderson (1981), also shown for comparison in Fig. 2.79, forms the basis for many current studies on global Earth's structure using quantitative exploitation of seismic waveforms at longer periods. It is the objective of the 'Working Group on Reference Earth models' in the 'IASPEI Commission on Earth Structure and Geodynamics' to retrieve a new 1-D reference Earth model for many depth-depending parameters which is also in agreement with observations of the Earth's normal modes.

The IASPEI 1991 Seismological Tables (Ed. Kennett, 1991) are now out of print. The more recent global P- and S-wave velocity and density model AK135, and the related body wave travel-time tables and plots are available via <http://rses.anu.edu.au/pub/ak135> and can be downloaded or printed in postscript. Additionally, software for travel-time routines and for corrections of the ellipticity of the Earth can be obtained via <http://rses.anu.edu.au/seismology/ttsoft.html>.

### **2.7.2 3-D models and their use in event location**

To first order, the structure of the Earth is dominated by its radial structure. However, important deviations between observed and theoretical travel times of seismic waves with respect to 1D-reference models cannot be explained by these simple 1D models. These differences, though relatively small (<10%) are due to the existence of lateral heterogeneities of physical properties within the different layers of the Earth. The determination of 3D models of seismic parameters of the mantle (also coined tomographic models) consists in imaging the structure of convection in order to provide clues to the nature of the driving mechanism and to investigate mantle convective processes, the engine of plate tectonics. Thanks to the intensive use of computers which can handle very large data sets, the techniques of seismic tomography can image the 3D deep structure of the Earth and provide unavoidable constraints of possible models of mantle convection and makes it possible to test different competing hypotheses. However, the main limitation of seismic tomography is that it only provides an instantaneous image of our planet Earth and it is necessary to confront seismic results with other earth science fields providing information on the history of our planet.

Seismic wave propagation is very sensitive to temperature, chemical, and mineralogical anomalies. These anomalies reflect the active dynamics of the Earth. It was observed for many decades that seismic velocity below old continents is much larger than the velocity beneath young oceans. This difference between tectonic provinces can be explained by a different history: cratons older than 1 billion years had a lot of time to get colder, whereas below oceans, the younger and warmer lithosphere is permanently recycled within the mantle. An increase in temperature is usually translated into decrease in seismic velocity, whereas an increase in pressure is translated into velocity increase. At a given depth (approximately constant pressure), the lateral variations of seismic velocity can be primarily interpreted in terms of temperature variations. A large variety of tomographic techniques similar to ultra-sonography or scanner have been developed for getting the 3D structure of the Earth, notwithstanding the geological nature of the surface.

The first 3D models of the Earth's mantle were proposed by the end of the 1970s (for example, Dziewonski et al., 1977), but the true revolution of seismic tomography took place in the middle 1980s when a complete set of tomographic models was proposed from the surface down to the center of the Earth. The present lateral resolution at global scale for the whole Earth is approximately 1,000km. Tomographic models (Fig. 2.80) fundamentally renewed our vision of earth dynamics, and shed new light on deep processes. At 100km depth, the distribution of seismic velocity anomalies reflects the geological surface structure. Almost all plate boundaries are slow since they are often associated with active volcanism. In oceanic zones, seismic velocity increases with the age of the sea floor confirming the cooling of plates with age. This remarkable agreement between observed seismic structure and structure deduced from geology was the first proof of the validity of the tomographic approach. At larger depths, the correlation between surface geology and seismic structure progressively vanishes and the amplitude of seismic anomalies decreases. The continental roots can be found down to 250-300km but mid-ocean ridges are no longer visible. In contrast, subducting slabs associated with high velocities can be traced down very deeply. The transition zone (410-660km) is still one of the less well-resolved depth ranges. It is characterized by weak heterogeneities but the velocity distribution is dominated by a simple scheme, with high velocities around the Pacific ocean and slow velocities below central Pacific and Africa, the so-called “degree 2” pattern (Masters et al., 1982).

The behaviour of slabs in regional studies does not seem to be uniform (Fig. 2.81). Some slabs seem to fall down to the core-mantle boundary (van der Hilst, et al., 1997), whereas others, e.g. beneath Japan (Fukao et al, 2001) are stagnant in the transition zone. Mantle plumes and the associated hotspots might initiate continental breakup, inducing the opening of new ridges of oceans, and might dramatically affect biodiversity. After plate tectonics, plume tectonics? There is still a controversy on the origin of plumes. It is likely that they do not have a single origin, but can originate from the different boundary layers within the Earth, in the asthenosphere, transition zone and D''-layer. There are still lively debates about the origin at depth of mantle plumes and two opposite extreme models (plate model and plume model) have been proposed. At the base of the mantle, the D''-layer is still very mysterious since it is the probable graveyard of slabs and a good candidate for being the matrix of some mantle plumes giving birth to hotspots at the surface of the Earth.

For sake of mathematical simplicity, it was usually assumed that the propagating elastic medium is isotropic, in spite of the large amplitude of anisotropy in several depth ranges. And only 1-D reference models of attenuation are incorporated in seismic modelling. Global tomographic models improved over years not only by an increase in the number of data but also by more general parameterizations. They are now including anisotropy, general slight anisotropy (for example, Montagner and Tanimoto, 1991), and anelasticity. Whereas isotropic heterogeneities enable one to map hot and cold regions within the Earth, seismic anisotropy gives access to the convective flow.

Impressive progress through global tomography, geochemistry and mineral physics has been made during the last twenty years in our understanding of global geodynamics, demonstrating how active and turbulent our planet is. All layers are heterogeneous, interact and exchange matter. The geosciences community must improve the lateral resolution and the quality of the 3D images and incorporate on a routine basis, anisotropy and anelasticity. There is a real need for a 3D seismic reference earth model in agreement with geological, mineralogical data, and fluid dynamics modelling.

**Fig. 2.80** Maps through S-velocity models SAW24B16, SB4L18, TXBW, and S2ORTS and P-velocity models P-MIT and FF-PRI at depths of 125, 600, 1350, and 2750 km (compiled by P. Bormann according to data published by Thurber and Ritsema, 2007).

**Fig. 2.81** Tomographic images of slabs (Top: van der Hilst et al., 1997) and plumes (Bottom: Montelli et al., 2004). **Blue colors** and **red colors** indicate positive and negative velocity perturbations to reference mantle velocities, respectively.

Currently almost all published earthquake catalogues have applied traditional, iterative linearized inversion schemes and 1-D Earth models to obtain event location and uncertainty parameters. Although there is a considerable effort to apply 3-D Earth models for travel time predictions, these methods and Earth models have yet to find their way into routine production of earthquake catalogs. Nevertheless, progress is being made.

In the local distance range ( $0^{\circ}$ – $2.5^{\circ}$ ) it has been shown (Bondar et al, 2004) that, using an accurate 1-D local velocity model and Pg and Sg arrival times recorded by a dense network of stations at distances less than about 250 km, one can achieve a location accuracy of 5 km or better at the 95% confidence level. However, at regional ( $2.5^{\circ}$ – $20^{\circ}$ ) distances lateral heterogeneity in the Earth's crust and uppermost mantle can severely affect Pn travel times to stations in that distance range, leading to location errors of 25 km or more when using a 1-D model. This has been a challenge to the test ban monitoring community, which has led to new developments in the use of 3-D models and azimuthally based station corrections to reduce location errors to as small as 5 km when using regional station arrival times to locate events in Eurasia.

When stations at teleseismic distances are used for location, P waves are travelling primarily in the Earth's lower mantle, with only 1-2% lateral heterogeneity, and location errors can be reduced to on average 15 km for earthquakes occurring in continental regions. However, in subduction zones location errors can be as large as several tens of km because of the effects of high velocity (+8 to 10%) downgoing slabs in the mantle. Only now are 3-D global models of regional and lower mantle structure being developed that can account for these effects, but for location applications these models require intensive ray tracing using high-speed computers for travel time prediction and phase identification.

## 2.8 Synthetic seismograms and waveform modeling

(R. Kind and P. Bormann)

A good measure of the advancement made by a scientific discipline is its ability to predict the phenomena with which it is dealing. One of the goals of seismology, as stated already over a hundred years ago by Emil Wiechert, is to understand every wiggle on the seismogram. This requires, as sketched in Fig. 1.1 of Chapter 1, an understanding and quantitative modeling of the contributions made to the seismic record (the output) by the various subsystems of the complex information chain: the source effects (input), the propagation effects (medium), the influence of the seismograph (sensor) and of the data processing. It is possible nowadays to model each of these effects quite well mathematically and thus to develop procedures for calculating *synthetic seismograms*. While the modeling of the seismometer response (see Chapter 5) and of the source effects (see 3.5 and IS 3.1) have been outlined in more detail in this Manual, it is beyond the scope of a handbook on observatory practice to go into the depth of wave propagation theory. Here we have to refer to pertinent textbooks such as Aki and Richards (1980 and 2002), Kennett (1983, 2001 and 2002), Lay and Wallace (1995), Dahlen and Tromp (1998) or, for some condensed introduction, to Shearer (1999). Below we will only sketch some of the underlying principles, refer to some fundamental approaches, discuss their potential and shortcomings and give a few examples of synthetic seismogram calculation and waveform modeling for near and teleseismic events.

Based on advanced theoretical algorithms and the availability of powerful and fast computers the calculation of synthetic seismograms for realistic Earth models is becoming more and more a standard procedure both in research and in advanced observatory routines. Such calculations, based on certain model assumptions and parameter sets for the source, propagation path and sensor/recorder are sometimes referred to as the solution of the *direct* or *forward problem* whereas the other way around, namely, to draw inferences from the observed data itself on the effects and relevant parameters of propagation path and source is termed the *inverse problem* (see Fig. 1.1). With the exception of a few specialized cases of direct analytical solutions to the inverse problem (such as using the Wiechert-Herglotz inversion [Eqs. (2.21) and (2.22)] for calculating the velocity-depth distribution of the medium from the observed travel-time curves), most inverse problems are solved by comparing synthetic data with observed ones. The model parameters are then changed successively in an iterative process until the differences between the observed and the synthetic data reach a minimum. The procedure of comparing synthetic and observed seismograms is known as *waveform modeling*. It can be used in routine practice for better identification of seismic phases and more reliable onset-time picking in case of noisy data. Additionally, more and more advanced seismological data centers, such as NEIC, now make use of waveform fitting for fast seismic moment tensor and other source parameter solutions, such as source depth (see 3.5.6.1).

The underlying mathematical tool for constructing synthetic seismograms is the *linear filter theory*. The seismogram is thus treated as the output of a sequence of linear filters, each accounting for relevant aspects of the seismic source, propagation path and sensor/recorder. Accordingly, the seismogram  $u(t)$  can be written as the result of convolution of three basic filters, namely:

$$u(t) = s(t) * g(t) * i(t), \quad (2.37)$$

where  $s(t)$  is the signal from the seismic source,  $g(t)$  is the propagation filter, and  $i(t)$  is the overall instrument response. These basic filters can in fact be broken down into various sub-filters, each accounting for specific effects of the source (such as source radiation directivity, source-time function), the propagation medium (such as structure and attenuation) or the instrument (such as sensor and recorder). This makes it possible to study in detail the effects of a specific parameter or process on the character of the seismogram, e.g., the effects of the shape and bandwidth of the seismograph response on the recording (see 4.2) or of the source depth, rupture orientation or time-history of the rupture process on the signal shape (see pp. 400-412 in Lay and Wallace, 1995). With respect to the propagation term in Eq. (2.37) it may be modelled on the basis of a full wave-theoretical approach, solving Eq. (2.5) for 1-D media consisting of stacks of homogeneous horizontal layers. The complete response of such series of layers may be described by matrixes of their reflection and transmission coefficients and a so-called *propagator algorithm* (Thomson, 1950 and Haskell, 1953) or by generalized reflection and transmission coefficients for the entire stack as in the reflectivity method by Fuchs and Müller (1971), Kennett (1983), Müller (1985). Another, ray theoretical approach (e.g., Červený et al., 1977; Červený, 2001) is possible when assuming that variations in the elastic parameters of the media are negligible over a wavelength and thus these gradient terms tend to zero at high frequencies. While pure ray tracing allows one only to model travel-times, the assumption of so-called "*Gaussian beams*", i.e., "ray tubes" with a Gaussian bell-shaped energy distribution, permits the modeling of both travel-times and amplitudes and thus to calculated complete synthetic seismograms also for non-1-D structures.

While a decade ago limited computer power allowed one to model realistically only relatively long-period teleseismic records, it is now possible to compute complete short-period seismograms of up to about 10 Hz or even higher frequencies. Several program packages (e.g. Fuchs and Müller, 1971; Kind, 1978; Kennett, 1983; Müller 1985; Sandmeier, 1990; Wang, 1999) permit one to compute routinely for given source parameters and, based on 1-D Earth models, synthetic seismograms for both near field and teleseismic events.

Two examples of synthetic seismogram sections in reduced travel-time presentation are shown below. Fig. 2.82 shows records for the local/regional distance range between 50 and 350 km with P, S and surface waves in the frequency range between about 0.5 and 2 Hz. Fig. 2.83 compiles synthetic records for longitudinal and some converted phases with frequencies between about 0.1 and 0.3 Hz in the teleseismic distance range between 32° and 172°. The earth-flattening approximation of Müller (1977) is used to transform the flat layered model into a spherical model. This approximation does not permit calculation of phases travelling close to the center of the Earth. The theoretical record sections are noise-free and have simpler waveforms than most real seismograms, owing to the assumption of a simple source function. Fig. 2.82 does not show signal-generated codas of scattered waves that are so typical for short-period records of local events.

**Fig. 2.82** Synthetic seismogram sections in the distance range 50-350 km, calculated for a hypothetical explosive source at 6 km depth in a homogenous single layer crustal model of 30 km thickness. For the calculation the program by Kind (1978) was used.

**Fig. 2.83** Long-period synthetic seismic record section for the epicenter distance range 36°-166°, assuming a surface explosion and wave-propagation through the IASP91 model (Kennett and Engdahl, 1991). For the calculation the program by Kind (1978) was used.

The synthetic record sections shown in Figs. 2.82 and 2.83 provide some general insights into basic features of seismograms in these two distance ranges such as:

- The overcritical Moho reflections PmP have the largest amplitudes in the P-wave part of near seismic recordings, with maximum amplitudes near the critical point around 70 km;
- Pg is the first arrival up to about 140 km (for a crustal thickness of 30 km) with amplitudes decaying rapidly with distance in this simple model example;

- Since the travel-time curve of PmP approaches that of Pg asymptotically for larger distances, it may be difficult to separate Pg from Pm in real Earth for distances larger than about 100 km (see Fig. 2.67);
- Pn takes over as first arrival beyond about 140 km with generally rather weak amplitudes and higher apparent velocity;
- Sg (and in case of shallow events also surface waves, e.g., Rg) has (have) much larger amplitudes than the various types of direct, refracted or reflected P waves in records of local/regional events;
- The core shadow due to the strongly reduced P-wave velocities in the outer core is indeed clearly developed at epicenter distances between about 100° and 140°, however, long-period diffracted P waves may still be observable as relatively weak first arrivals up to 120° and more;
- PP is the first strong wave arrival in the core shadow range and, if Pdif or the weak inner-side reflections of P from the 660km or 410 km discontinuities (phase names P660-P and P440-P, respectively) are buried in the noise, PP can easily be misinterpreted as P-wave first arrival;
- The caustic of PKP around 145° produces very strong amplitudes comparable to those of P between about 50° to 70°;
- The branching of PKP into three travel-time branches beyond the caustic is well reproduced in the synthetic seismograms;
- Converted core reflections (PcS) and converted core refractions (PKS) may be rather strong secondary later arrivals in the P-wave range between about 35°-55° and in the core-shadow range between about 120°-140°, respectively.

The following figures illustrate the potential of waveform modeling. Depth phases are not only very useful for determining the focal depth from teleseismic records, they are also frequently observed at regional distances and permit accurate depth determinations. Fig. 2.84 shows the ray paths for the phases Pn, pPn, sPn, pPnS and sPmP in a single layer crust from an event at depth  $h$ , as recorded in the distance range beyond 150 km, when Pn appears as the first arrival. Fig. 2.85 (left) shows the theoretical seismograms for these phases at a distance of 210 km and as a function of source depth. It is easy to identify the depth phases. Fig. 2.85 (right) presents a compilation of the summation traces of all available vertical component records of the Gräfenberg array stations for the 1978 Swabian Jura (Germany) earthquake (September 3, 05:09 UT;  $M_L = 6.0$ ) and for several of its aftershocks. All these events have been recorded at an epicenter distance of about 210 km. Depth phases sPn were observed in most records. From the correlation of sPn in neighboring traces it becomes obvious that the source depth migrated within 5 hours from the main shock at  $h = 6.5$  km to a depth of only about 2-3 km for the aftershock at 10:03 UT.

**Fig. 2.84** Ray paths of local depth phases (for synthetics and records see Fig. 2.85).

**Fig. 2.85** **Left:** Theoretical seismograms in reduced travel-time presentation at 210 km epicenter distance as function of source depth for a single-layer crust of 30 km thickness. A clear depth phase  $sP_n$  is recognizable between  $P_n$  and  $P_g$ ; **right:** Gräfenberg records of Swabian Jura events in southern Germany. Epicenter distance is 210 km. Between the  $P_n$  and  $P_g$  arrival, a clear depth phase  $sP_n$  can be observed. These observations indicate that after the main shock on September 3 at 05:09 the aftershocks migrated from 6.5 km depth to 2-3 km depth within 5 hours (from Kind, 1985).

Langston and Helmberger (1975) studied the influence of hypocenter depth  $h$ , type of source mechanism, source-time function and of stress drop on seismic waveforms. The superposition of  $P$ ,  $pP$  and  $sP$ , which follow close one after another in the case of crustal earthquakes, make it difficult to separate these individual phases properly in more long-period teleseismic records and to pick the onset times of the depth phases reliably. However, because of the pronounced changes in the waveform of this  $P$ -wave group as a function of depth, one may be able to constrain also the source depth of distant earthquakes rather well by waveform modeling with an accuracy of about 5 km. On the other hand, one should be aware that there is a strong trade-off between source depth and the duration of the source-time function. A deeper source with source function of shorter duration may be similar to a shallower source with a longer source function. For simple sources, broadband data may help to overcome much of this trade-off. For complex source functions, however, these may trade-off with differences in source depth if only data from single stations are available. Using data from several stations instead could reduce this problem.

Generally, waveform modeling is much more powerful than first-motion focal mechanism determinations (see 3.4) in constraining fault orientation. Even with only a few stations and limited azimuthal coverage around the source superior results may be achieved. This is of particular importance for a fast determination of source parameters. Additionally, by comparing predicted and observed amplitudes of waveforms, the seismic moment can be determined rather reliably (see 3.5). Fig. 2.86 shows an example of waveform modeling in the

teleseismic distance range for records of the 1989 Loma Prieta earthquake in different azimuth around the source. From the best fitting synthetics, the source-time function, fault strike  $\phi$ , dip  $\delta$ , rake  $\lambda$  and seismic moment  $M_0$  were estimated. However, Basham and Kind (1986) could show that even with the broadband data from only one teleseismic station good estimates of fault depth, strike, dip and rake could be derived from waveform modeling.

**Fig. 2.86** Results of waveform modeling for the 1989 Loma Prieta earthquake. Depicted are the pairs of observed (top trace) and synthetic waveforms (bottom trace) for long-period Pn (left column), teleseismic P (middle column) and SH waves (right column). The time function used is shown at the lowermost right side. From the inversion of these data the following source parameters were determined:  $\phi = 128^\circ \pm 3^\circ$ ,  $\delta = 66^\circ \pm 4^\circ$ ,  $\lambda = 133^\circ \pm 7^\circ$ , and the moment  $M_0 = 2.4 \times 10^{19}$  Nm (reproduced from Wallace et al., 1991, A broadband seismological investigation of the 1989 Loma Prieta, California, earthquake: Evidence for deep slow slip? Bull. Seism. Soc. Am., Vol. 81, No. 5, Fig. 2, page 1627; 1991; © Seismological Society of America).

## Acknowledgments

The authors thank P. Shearer, P. Malischewsky and J. Schweitzer for careful proof-reading of the first edition and P. Malischewsky also of the amended second edition of this Chapter, and many valuable suggestions. Thanks go also to M. Baumbach, B. L. N. Kennett, D. Di Giacomo, K. Klinge, P. Malischewsky, H. Neunhöfer, P. Richards, J. Ritsema, B. Schurr, J. Schweitzer S. Wendt and K. Wylegalla for making some figures or related data for their production available.

Below, data and background information on the most frequently used 1-D Earth reference models in global seismology have been compiled by using Appendix 1 of Shearer (1999), Kennett (1991) and personal information received from B. Kennett (2002).

## 1 PREM Model

For many years the most widely used 1-D model of seismic velocities in the Earth has been the Preliminary Reference Earth Model (PREM) of Dziewonski and Anderson (1981). This model was designed to fit a variety of different data sets, including free oscillation center frequency measurements, surface-wave dispersion observations, travel-time data for a number of body-wave phases, and basic astronomical data (Earth's radius, mass, and moment of inertia). Table 1 summarizes, as functions of depth and Earth's radius, the PREM velocities  $v_p$  and  $v_s$  for P and S waves, the density  $\rho$ , the shear and bulk quality factors,  $Q_\mu$  and  $Q_\kappa$ , and the pressure  $P$ . Note, that density and attenuation ( $\sim 1/Q$ ) are known less precisely than the seismic velocities but these parameters are required for computing synthetic seismograms. In order to simultaneously fit Love- and Rayleigh-wave observations, PREM is transversely isotropic between 80 and 220 km depth in the upper mantle. Transverse isotropy is a spherically symmetric form of anisotropy in which SH and SV waves travel at different speeds. Table 1, however, lists only values from an isotropic version of PREM. The true PREM model is also specified in terms of polynomials between node points. Linear interpolation between the values given in Table 1 will produce only approximate results. All current Earth models have values that are reasonably close to PREM. The largest differences are in the upper mantle where PREM shows a discontinuity at 220 km which is not found in most other models. Fig. 2.53 in Chapter 2 depicts PREM together with the more recent model AK135 (see Table 3 below).

**Table 1 Preliminary Reference Earth Model (isotropic version)**

| Depth (km) | Radius (km) | $v_p$ (km/s) | $v_s$ (km/s) | $\rho$ (g/cm <sup>3</sup> ) | $Q_\mu$ | $Q_\kappa$ | $P$ (GPa) |
|------------|-------------|--------------|--------------|-----------------------------|---------|------------|-----------|

## 2 IASP91 velocity model

According to Kennett (1991) and Kennett and Engdahl (1991), the IASP91 model is a parameterized velocity model, in terms of normalized radius. It has been constructed to be a summary of the travel-time characteristics of the main seismic phases.

The crust consists of two uniform layers with discontinuities at 20 and 35 km. Between 35 and 760 km the velocities in each layer are represented by a linear gradient in radius. The major mantle discontinuities are set at 410 km and 660 km. The upper mantle model is designed for the specific purpose of representing the 'average' observed times for P and S waves out to 30° as well as providing a tie to teleseismic times. Since the distribution of seismic sources and recording stations is far from uniform, the IASP91 model will include geographical bias as well as the constraints imposed by the specific parameterization.

The distribution of P- and S-wave velocities,  $v_p$  and  $v_s$ , in the lower mantle is represented by a cubic radius between 760 km and 2740 km. The velocities in the lowermost mantle are taken as a linear gradient in radius down to the core-mantle boundary at 3482 km. In the core and inner core the velocity functions are specified as quadratic polynomials in radius.

Table 2.1 presents the parameterized form and Table 2.2 the tabulated form of the IASP91.

**Table 2.1 Parameterized form of the IASP91 model**

( $x$  = normalised radius  $r/a$  where  $a = 6371$  km)

| Depth<br>(z km) | Radius<br>(r km) | $v_p$<br>(km/s) | $v_s$<br>(km/s) |

### 3 Model AK135

The AK135 velocity model has been augmented with a density and Q model by combining the study of travel times with those of free oscillations. This velocity and density model is the product of two pieces of work.

(1) The velocity model below 120 km depth comes from the work of Kennett et al. (1995). The original continental structure for the uppermost layering is given in Tab. 3.1 below. This model probably gives a reasonable representation of spherically averaged structure below 760 km depth. The upper mantle, as in IASP91, is an artificial construct which gives a good fit to the ensemble of observed travel times out to 30 degrees. The structure in D" should also be regarded as representative.

The representation of the velocity model is via point-wise values in velocity and linear interpolation in radius is used as the basis of the travel-time calculations. Note that AK135, unlike IASP91, is not a parameterized model. Any suitable interpolation scheme may be used where appropriate. A software conversion is available for reading velocity models into the IASP travel-time software and ellipticity corrections have been constructed for all the phases represented by that software. The software can be obtained from <http://rses.anu.edu.au/seismology/ttsoft.html>.

(2) Modified density and Q models come from a study by Montagner and Kennett (1996). This study introduces a density model and Q to the velocity distribution from the travel-time work to try to fit observations of free oscillation frequencies. An averaged uppermost structure is imposed on the AK135 velocities. The version of the model represented here is isotropic, even though the paper investigates the inclusion of anisotropy as well.

The complex density structure in the upper mantle with a density inversion reflects the absence of a low velocity zone in the wave-speed model. For a spherical average either a low shear-wave zone or a low density zone is needed to match the free oscillation frequencies. The Q values are those needed to bring the 1 Hz travel-time velocities into a match with the free oscillations and also give a good fit to observed Q values for the normal modes.

NB: The upper mantle density model should be treated with caution and may well change with further work.

**Table 3 AK135 velocity model for travel times**

#### 3.1 Continental structure

| Depth<br>(km) | $v_p$<br>(km/s) | $v_s$<br>(km/s) |
|---------------|-----------------|-----------------|
| 0.000         | 5.8000          | 3.4600          |
| 20.000        | 5.8000          | 3.4600          |
| 20.000        | 6.5000          | 3.8500          |
| 35.000        | 6.5000          | 3.8500          |
| 35.000        | 8.0400          | 4.4800          |
| 77.500        | 8.0450          | 4.4900          |
| 120.000       | 8.0500          | 4.5000          |

### 3.2 Average structure

| Depth<br>(km) | Density<br>(g/cm <sup>3</sup> ) | v <sub>p</sub><br>(km/s) | v <sub>s</sub><br>(km/s) | Q <sub>α</sub> | Q <sub>μ</sub> |
|---------------|---------------------------------|--------------------------|--------------------------|----------------|----------------|
| 0.00          | 1.0200                          | 1.4500                   | 0.0000                   | 57822.00       | 0.00           |

**Table 3.2 (continued)**

| Depth<br>(km) | Density<br>(g/cm <sup>3</sup> ) | v <sub>p</sub><br>(km/s) | v <sub>s</sub><br>(km/s) | Q <sub>α</sub> | Q <sub>μ</sub> |
|---------------|---------------------------------|--------------------------|--------------------------|----------------|----------------|
| 6269.57       | 13.0100                         | 11.2606                  | 3.6667                   | 601.46         | 85.03          |
| 6320.29       | 13.0117                         | 11.2618                  | 3.6675                   | 601.32         | 85.03          |
| 6371.00       | 13.0122                         | 11.2622                  | 3.6678                   | 601.27         | 85.03          |

**Note:** The bulk Q<sub>κ</sub> given in Table 1 differs from the Q<sub>α</sub> for P waves given in Table 3.2. The following relationship holds:

$$Q_{\alpha}^{-1} = L Q_{\mu}^{-1} + (1 - L)Q_{\kappa}^{-1}$$

where  $L = (4/3)(\beta/\alpha)^2$ ,  $\alpha$  = P-wave velocity v<sub>p</sub> and  $\beta$  = S-wave velocity v<sub>s</sub>. However, Q<sub>μ</sub> = Q<sub>β</sub> for S waves and Q<sub>α</sub> = Q<sub>κ</sub> in the liquid outer core because of  $\mu$  and Q<sub>μ</sub> = 0.

## 1 Introduction

A Working Group (WG) on Standard Phase Names was set up by the IASPEI Commission on Seismological Observation and Interpretation in 2001. The working group was chaired by D. A. Storchak of the ISC. Members of the group were R. D. Adams, P. Bormann, R. E. Engdahl, J. Havskov, B. L. N. Kennett and J. Schweitzer. The working group has put together a modified standard nomenclature of seismic phases, which was meant to be concise, consistent and self-explanatory on the basis of agreed rules. The result is not a complete list of all phases. The list is not meant to satisfy specific requirements of seismologists to name various phases used in a particular type of research. Instead, the new phase list aims at inviting data analysts and other users to ensure an expanded standardized data reporting and

exchange. This will result in a broader and unambiguous database for research and practical applications. At the same time the attached list and its principles outlined below may be a useful guidance when proposing names to previously unknown seismic phases.

After numerous consultations with the seismological community, the Standard Seismic Phase List was finalized and adopted by the CoSOI/IASPEI at its meeting in Sapporo on July 04, 2003. The original draft list of standard seismic phase names was first published as part of the New Manual of Seismological Observatory Practice (Storchak et al., 2002). Later on, the list was published in the Seismological Research Letters (Storchak et al., 2003). Since then various updates to the list were required due to progress in observational seismology and relevant changes in other observational standards. These changes were accommodated in a contribution by Storchak et al. (2011) to the Encyclopedia of Solid Earth Geophysics. The current amended version of IS 2.1 takes all these updates into account. Moreover, it aims at unifying some wording in the definitions. The List should be used as a guide to identify such phases in real seismic records by taking into account additional resources provided in DS11.1 to DS11.4 of the NMSOP-2.

The new IASPEI nomenclature partially modifies and complements the earlier one published in the last edition of the Willmore (1979) Manual of Seismological Observatory Practice and in the Summaries of the Bulletin of the International Seismological Centre (2010). It is more in tune with phase definitions according to modern Earth and travel-time models (see Chapter 2, section 2.7) and the definition of pronounced travel-time branches, of core phases in particular (see manual sections 11.5.2.4 and 11.5.3). As opposed to former practice, the WG tried to make sure that a phase name generally reflects the type of the wave and the path it has traveled. Accordingly, symbols for characterizing onset quality, polarity etc. are no longer part of the phase name. Also, the WG acknowledges that there exist several types of seismic phases, particularly among crustal phases, that are common in some regions yet never or rarely found in other regions, such as, e.g., Pb (P\*), PnPn, PbPb, etc. The names and definitions of acoustic and hydroacoustic phases and amplitude measurement are likely to be reviewed based on the results of recent developments and new analysis practices being established.

The extended list of phase names, as presented below in section 5, accounts for significantly increased detection capabilities of modern seismic sensors and sensor arrays, especially for weak phases that were rarely found using the classical analog records. It also accounts for improved possibilities of proper phase identification by means of digital multi-channel data processing such as frequency-wavenumber (f-k) analysis and polarization filtering, by modeling the observations with synthetic seismograms or by showing on the records the theoretically predicted onset times of phases. Furthermore, limitation of classical formats for wave parameter reporting to international data centers, such as the Telegraphic Format (TF), which allowed only the use of capital letters and numbers, are no longer relevant in times of data exchange via the Internet. Finally, the newly adopted IASPEI Seismic Format (ISF; see <http://www.isc.ac.uk/standards/isf/download/isf.pdf>, Chapter 10, section 10.2.5 and IS 10.2) is much more flexible than the old formats accepted by the NEIC, ISC and other data centers. It also allows reporting, computer parsing and archiving of all phases, including previously uncommon ones. The ISF also accepts complementary parameters such as onset quality, signal-to-noise ratio, measured backazimuth and slowness, amplitudes and periods of other phases in addition to P and surface waves, for components other than vertical ones, and for non-standard response characteristics.

This increased flexibility of the parameter-reporting format requires improved standardization, which limits an uncontrolled growth of incompatible and ambiguous parameter data. Therefore, the WG agreed on certain rules. They are outlined below prior to the listing of standardized phase names. In order to ease the understanding of verbal definitions of the phase names and ray diagrams are presented. The ray diagrams have been calculated for local seismic sources on the basis of an average one-dimensional two-layer crustal model and for regional and teleseismic sources by using the global, radial symmetrical Earth model *ak135* (Kennett et al., 1995; see also Fig. 2.79).

Before elaborating short-cut seismic phase names one should agree first on the *language* to be used and its rules. As in any other language we need a suitable alphabet (here Latin letters), numbers (here Arabic numbers and + and - signs), an *orthography*, which regulates, e.g., the use of capital and lower case letters, and a *syntax*, i.e., rules of correct order and mutual relationship of the language elements. One should be aware, however, that the seismological nomenclature will inevitably develop exceptions to the rules, as any historically developed language, and also depending on the context in which it is used. Although not fully documented below, some exceptions will be mentioned. Note that our efforts are mainly aimed at standardized names to be used in international data exchange so as to build up unique, unambiguous global databases for research. Many of the exceptions to the rules are related to specialized, mostly local research applications. The identification of related seismic phases often requires specialized procedures of data acquisition and processing, which are not part of seismological routine data analysis. Also, many of these *exceptional* phases are rarely or never used in seismic event location, magnitude determination, source mechanism calculations etc., which are the main tasks of international data centers. Below, we focus therefore on phases, which are particularly important for seismological data centers as well as for the refinement of regional and global Earth models on the basis of widely exchanged and accumulated parameter readings from such phases. In addition, we added for some phase definitions references to which the particular phase names can be traced back.

## 2 Standard letters, signs and syntax used for describing seismic phases

### 2.1 Capital letters

Individual capital letters that stand for primary types of seismic *body waves* such as:

- P: longitudinal wave that has traveled through the Earth's crust and mantle, from *undae primae* (Latin) = first waves (Borne, 1904);
- K: longitudinal wave that has traveled through the Earth's outer core, K, from Kern (German) = core (Sohon, 1932; Bastings, 1934);
- I: longitudinal wave that has traveled through the Earth's inner core (Jeffreys and Bullen, 1940);
- S: transverse wave that has traveled through the Earth's crust and mantle, from *undae secundae* (Latin) = second waves (Borne, 1904);
- T: wave that has partly traveled as sound wave in the sea, from *undae tertiae* = third waves (Linehan, 1940);
- J: transverse wave that has traveled through the Earth's inner core (Bullen, 1946).

**Exceptions:**

- A **capital letter N** used in the nomenclature does not stand for a phase name but rather for the number of legs traveled (or N-1 reflections made) before reaching the station. N should usually follow the phase symbol to which it applies. For examples see syntax below.
- The **lower case letters p and s** may stand, in the case of seismic events below the Earth's surface, for the relatively short **upgoing leg** of P or S waves, which continue, after reflection and possible conversion at the free surface, as downgoing P or S wave. Thus seismic *depth phases* (e.g., pP, sP, sS, pPP, sPP, pPKP, etc.) are uniquely defined. The identification and reporting of such phases is of utmost importance for source depth determination (Scrase, 1931; Stechschulte, 1932; Gutenberg et al., 1933; Macelwane et al., 1933).
- Many researchers working on detailed investigations of crustal and upper-mantle discontinuities denote both the up- and downgoing short legs of converted or multiply reflected P and S phases as lower case letters p and s, respectively.

Individual or double capital letters that stand for *surface waves* such as:

- L: (relatively) long-period surface wave, unspecified, from *undae longae* (Latin) = long waves (Borne, 1904);
- R: Rayleigh waves (short- to very long-period waves in crust and upper mantle) (Angenheister, 1921);
- Q: Love waves, from Querwellen (German) = transverse waves (Angenheister, 1921);
- G: (very long-period) global (mantle) Love waves, firstly observed and reported by Gutenberg and Richter (1934); in honor of Gutenberg, Byerly proposed the usage of G for Gutenberg for these waves Richter (1958);
- LR: long-period Rayleigh waves, usually relating to the Airy-phase maximum in the surface wave train;
- LQ: long-period Love waves.
- PL: fundamental leaking mode following P onsets, firstly observed and reported by Somville (1930, 1931)

## 2.2 Lower case letters and signs

*Single lower case letters* generally specify in which part of Earth's crust or upper mantle in which a phase has its *turning point* or at which discontinuity it has been *reflected and/or eventually converted*:

- g (following a general phase name): characterizes waves "bottoming" (i.e., having their turning point in the case of P- or S-body waves) or just travel (surface waves) within the upper ("granitic") Earth's crust (e.g., Pg, Sg; Rg), (Jeffreys, 1926);
- b (following a general phase name): characterizes body waves "bottoming" in the lower ("basaltic") Earth's crust (Jeffreys, 1926) (e.g., Pb, Sb; alternative names for these phases are P\*, S\*, (Conrad, 1925)); also used for phases radiated directly to the Earth's surface from events in the lower crust;
- n (following a general phase name): characterizes a P or S wave that is "bottoming" in the Earth's uppermost mantle or is traveling as head wave below the

Mohorovičić (Moho) discontinuity (e.g., Pn, Sn), introduced after Andrija Mohorovičić discovered the Earth's crust and separated the crustal travel-time curve from the normal (=n) mantle phase (Mohorovičić, 1910); also used for phases radiated directly to the Earth's surface from events in the uppermost mantle;

- m: (upward) reflections from the *outer side* of the Moho (e.g., PmP, SmS);
- c: reflections from the *outer side* of the core-mantle boundary (CMB), usage proposed by James B. Macelwane (see Gutenberg, 1925);
- i: reflections from the *outer side* of the inner core boundary (ICB);
- z: reflections from a discontinuity (other than free surface, CMB or ICB) at depth z (measured in km). Upward reflections from the *outer side* of the discontinuity *may* additionally be complemented by a + sign (e.g., P410+P; this, however, is not compulsory) while downward reflections from the *inner side* of the discontinuity *must* be complemented by a – sign (e.g., P660–P).

An exception from these rules is the use of lowercase p or s to indicate arrivals of longitudinal or transverse waves that were from a source below the Earth's surface first radiated to go up toward the free surface to be reflected / converted back into the Earth as normal P or S waves (see near source surface reflections and conversions section of the phase list below).

To call phases radiated directly to the Earth's surface in the near source region from events in the lower crust (Conrad discontinuity) Pb and from below the Moho Pn is a quite pragmatic decision, which helps analysts and source location programs to separate the different branches of the travel-time curves.

*Double lower case letters* following a capital letter phase name indicate the travel-time branch to which this phase belongs. Due to the geometry and velocity structure of the Earth the same type of seismic wave may develop a triplication of its travel-time curve with different, in some cases well separated branches (see Chapter 2, Fig. 2.32). Thus it is customary to differentiate between different branches of core phases and their multiple reflections at the free surface or the CMB. Examples are PKPab, PKPbc, PKPdf, SKSac, SKKSac, etc.. The separation of the different PKP branches with letters ab, bc and df was introduced by Jeffreys and Bullen (1940).

*Three lower case letters* may follow a capital letter phase name in order to specify its character, e.g., as a forerunner (pre) to the main phase, caused by scattering (e.g., PKPpre) or as a diffracted wave extending the travel-time branch of the main phase into the outer core shadow (e.g., Pdif in the outer core shadow for P).

## 2.3 Syntax of generating complex phase names

Due to refraction, reflection and conversion in the Earth most of phases have a complex path history before they reach the station. Accordingly, most phases cannot be described by a single capital letter code in a self-explanatory way. By combining the capital and lower case letters as mentioned above, one can describe the character of even rather complex refracted, reflected or converted phases. The order of symbols (syntax) regulates the sequence of phase legs due to refraction, reflection and conversion events in time (from left to right) and in space.

### 3 Examples for creating complex standard phase names

#### 3.1 Refracted and converted refracted waves

- PKP is a pure refracted longitudinal wave. It has traveled the first part of its path as P through crust and mantle, the second through the outer core, and the third again as P through mantle and crust. An alternative name for PKP is P' (Angenheister, 1921), which should be read as “P prime”.
- PKIKP (alternative to PKP<sub>df</sub>) is also a pure refracted longitudinal wave too. It has traveled as P the first part of its path through crust and mantle, the second through the outer core, the third through the inner core, and the fourth and fifth parts back again through outer core and mantle/crust.
- SKS is a converted refracted wave. It has traveled as a shear wave through crust and mantle, being converted into a longitudinal P wave when refracted into the outer core and converted back again into an S wave when entering the mantle.
- SKP or PKS are converted refracted waves with only one conversion from S to P when entering the core or from P to S when leaving the core, respectively.

#### 3.2 Pure reflected waves

- In the case of (downward only) reflections at the free surface or from the inner side of the CMB, the phase symbol is just repeated, e.g., PP, SS (Geiger, 1909), PPP, SSS, KK, KKK etc.
- In the case of (upward) reflections from the outer side of the Moho, the CMB, or the ICB, this is indicated by inserting between the phase symbols m, c or i, respectively, between the phase symbols, e.g., PmP, PcP, ScS; PKiKP.
- Reflections from any other discontinuity in mantle or crust at depth z may be from the inner side (-; i.e., downward back into the mantle) or from the outer side (+; i.e., back towards the surface). To differentiate between these two possibilities, the sign has to follow z (or the respective number in km); for example, P410+P or P660-P.
- To abbreviate names of multi-leg phases due to repeated reflections, one can also write PhasenameN. This kind of abbreviation, is rather customary in the case of multiple phases with long phase names such as PmP2 for PmPPmP (free-surface reflection of PmP), SKS2 for SKSSKS (alternative name for S'2, the free-surface reflection of SKS), PKP3 for PKPPKPPKP (double free-surface reflection of PKP; alternative name to P'3) or P4KP for PKKKKP (triple reflection of P at the inner side of the CMB).

**Note 1:** PKP2 = PKPPKP are now alternative names for P'2 or P'P', respectively. This should not be mistaken for the *old* name PKP2 for PKPab.

**Note 2:** In the case of multiple reflections from the inner side of the CMB the WG followed the established tradition of placing the number N not after but *in front* of the related phase symbol K.

### 3.3 Reflected waves with conversion at the reflection point

In the case that a phase changes its character from P to S, or vice versa, one writes:

- PS (first leg P, second leg S) or SP (first leg P, second leg S) in the case of reflection/conversion from the free surface downward into the mantle (Geiger and Gutenberg, 1912a, 1912b);
- PmS or SmP, respectively, for reflection/conversion from the outer side of the Moho;
- PcS or ScP for reflection/conversion from the outer side of the CMB;
- Pz+S or Sz-P for reflection/conversion from the outer (+) side or inner (-) side, respectively, of a discontinuity at depth  $z$ . Note that the - is compulsory, the + not.

In this context it is worth mentioning that mode conversion is impossible for reflections from the inner side of the CMB back into the outer core because the liquid outer core does not allow the propagation of S waves.

The WG determined the new IASPEI standard phase names along these lines and rules. Where these deviate from other traditionally used names the latter are given as well. Either, the traditional names are still acceptable *alternative names* (alt) or they are now *old names* (old), which should no longer be used.

## 4 Ray-paths diagrams for some of the IASPEI standard phases

In this section we show ray paths through the Earth for most of the mentioned phases. The three figures for crustal phases are just sketches showing the principal ray paths in a two-layer crust. The rays in all other figures were calculated by using the ray picture part of the WKB3 code (Chapman, 1978; Dey-Sarkar and Chapman, 1978); as velocity model we chose the standard Earth model *ak135* (Kennett et al., 1995). For some types of P and S phases the ray paths through the Earth are very similar because the velocity ratio  $v_P/v_S$  does not change enough to give very different ray pictures. In these cases, we calculated only the ray paths for the P-type ray (i.e., P, Pdif, pP, PP, P3, PcP, PcP2, P660P and P660-P) and assume that the corresponding ray paths of the respective S-type phases are very similar. To show the different ray paths for phases with similar phase names, we show on many figures rays leaving the source once to the left and once to the right in different colors. The three most important discontinuities inside the Earth are indicated as black circles (i.e., the border between upper and lower mantle, the CMB, and the ICB).

#### 4.1 Seismic rays of crustal phases

**Figure 1** Seismic rays of „crustal phases“ observed in the case of a two-layer crust in local and regional distance ranges ( $0^\circ < D < \text{about } 20^\circ$ ) from the seismic source in the: a) upper crust; b) lower crust; and c) uppermost mantle.

## 4.2 Seismic rays of mantle phases

**Note:** The density of seismic rays arriving at a given location is proportional to the relative amplitude of the respective seismic phase observed at this location.

**Figure 2** Mantle phases observed at the teleseismic distance range  $D > \text{about } 20^\circ$ .

**Figure 3** Reflections from the Earth's core.

#### 4.3 Seismic rays of phases travelling through the Earth's core

**Figure 4** Seismic rays of direct core phases

**Figure 5** Seismic rays of single-reflected core phases

**Figure 6** Seismic rays of multiple-reflected and converted core phases.

## 5 IASPEI Standard Seismic Phase List

### 5.1 CRUSTAL PHASES (For ray traces see Figure 1; for more examples see Chapter 2, section 2.6.1; Chapter 11, section 11.5.1, DS 11.1 and EX 11.1)

|      |                                                                                                                                                                                                                                                                                     |
|------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Pg   | At short distances, either an upgoing P wave from a source in the upper crust or a P wave bottoming in the upper crust. At larger distances also arrivals caused by multiple P-wave reverberations inside the whole crust with a group velocity around 5.8 km/s                     |
| Pb   | (alt: P*) Either an upgoing P wave from a source in the lower crust or a P wave bottoming in the lower crust                                                                                                                                                                        |
| Pn   | Any P wave bottoming in the uppermost mantle or an upgoing P wave from a source in the uppermost mantle                                                                                                                                                                             |
| PnPn | Pn free-surface reflection                                                                                                                                                                                                                                                          |
| PgPg | Pg free-surface reflection                                                                                                                                                                                                                                                          |
| PmP  | P reflection from the outer side of the Moho                                                                                                                                                                                                                                        |
| PmPN | PmP multiple free-surface reflection; N is a positive integer. For example, PmP2 is PmPPmP                                                                                                                                                                                          |
| PmS  | P to S reflection/conversion from the outer side of the Moho                                                                                                                                                                                                                        |
| Sg   | At short distances, either an upgoing S wave from a source in the upper crust or an S wave bottoming in the upper crust. At larger distances also, arrivals caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust |
| Sb   | (alt: S*) Either an upgoing S wave from a source in the lower crust or an S wave bottoming in the lower crust                                                                                                                                                                       |
| Sn   | Any S wave bottoming in the uppermost mantle or an upgoing S wave from a source in the uppermost mantle                                                                                                                                                                             |
| SnSn | Sn free-surface reflection                                                                                                                                                                                                                                                          |
| SgSg | Sg free-surface reflection                                                                                                                                                                                                                                                          |
| SmS  | S reflection from the outer side of the Moho                                                                                                                                                                                                                                        |
| SmSN | SmS multiple free-surface reflection; N is a positive integer. For example, SmS2 is SmSSmS                                                                                                                                                                                          |
| SmP  | S to P reflection/conversion from the outer side of the Moho                                                                                                                                                                                                                        |
| Lg   | A wave group observed at larger regional distances and caused by superposition of multiple S-wave reverberations and SV to P and/or P to SV conversions inside the whole crust. The maximum energy travels with a group velocity around 3.5 km/s                                    |
| Rg   | Short-period crustal Rayleigh wave                                                                                                                                                                                                                                                  |

### 5.2 MANTLE PHASES (record and ray tracing examples see Chapter 2, section 2.6.2; Chapter 11, section 11.5.2; DS 11.2; EX 11.2 and animations from 42° up to 152° via IS 11.3)

|    |                                                                                                                                       |
|----|---------------------------------------------------------------------------------------------------------------------------------------|
| P  | A longitudinal wave, bottoming below the uppermost mantle; also an upgoing longitudinal wave from a source below the uppermost mantle |
| PP | Free-surface reflection of a P wave leaving a source downward                                                                         |

|      |                                                                                                                                                                                                   |
|------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| PS   | P, leaving a source downward, reflected as an S at the free surface. At shorter distances the first leg is represented by a crustal P wave                                                        |
| PPP  | Analogous to PP                                                                                                                                                                                   |
| PPS  | PP which is converted to S at the second reflection point on the free surface; travel time matches that of PSP                                                                                    |
| PSS  | PS reflected at the free surface                                                                                                                                                                  |
| PcP  | P reflection from the core-mantle boundary (CMB)                                                                                                                                                  |
| PcS  | P converted to S when reflected from the CMB                                                                                                                                                      |
| PcPN | PcP reflected from the free surface N-1 times; N is a positive integer. For example PcP2 is PcPPcP                                                                                                |
| Pz+P | (alt: PzP) P reflection from outer side of a discontinuity at depth z; z may be a positive numerical value in km. For example, P660+P is a P reflection from the top of the 660 km discontinuity  |
| Pz-P | P reflection from inner side of a discontinuity at depth z. For example, P660-P is a P reflection from below the 660 km discontinuity, which means it is precursory to PP                         |
| Pz+S | (alt: PzS) P converted to S when reflected from outer side of a discontinuity at depth z                                                                                                          |
| Pz-S | P converted to S when reflected from inner side of a discontinuity at depth z                                                                                                                     |
| PScS | P (leaving a source downward) to ScS reflection at the free                                                                                                                                       |
| Pdif | (old: Pdiff) P diffracted along the CMB in the mantle                                                                                                                                             |
| S    | Shear wave, bottoming below the uppermost mantle; also an upgoing shear wave from a source below the uppermost mantle                                                                             |
| SS   | Free surface reflection of an S wave leaving a source downward                                                                                                                                    |
| SP   | S, leaving a source downward, reflected as P at the free surface. At shorter distances, the second leg is represented by a crustal P wave.                                                        |
| SSS  | Analogous to SS                                                                                                                                                                                   |
| SSP  | SS converted to P when reflected from the free surface; travel time matches that of SPS                                                                                                           |
| SPP  | SP reflected at the free surface                                                                                                                                                                  |
| ScS  | S reflection from the CMB                                                                                                                                                                         |
| ScP  | S converted to P when reflected from the CMB                                                                                                                                                      |
| ScSN | ScS multiple free-surface reflection; N is a positive integer. For example ScS2 is ScSScS                                                                                                         |
| Sz+S | (alt: SzS) S reflection from outer side of a discontinuity at depth z; z may be a positive numerical value in km. For example S660+S is an S reflection from the top of the 660 km discontinuity. |
| Sz-S | S reflection from inner side of a discontinuity at depth z. For example, S660-S is an S reflection from below the 660 km discontinuity, which it is precursory to SS                              |
| Sz+P | (alt: SzP) S converted to P when reflected from outer side of a discontinuity at depth z                                                                                                          |
| Sz-P | S converted to P when reflected from inner side of a discontinuity at depth z                                                                                                                     |
| ScSP | ScS to P reflection at the free surface                                                                                                                                                           |
| Sdif | (old: Sdiff) S diffracted along the CMB in the mantle                                                                                                                                             |

---

### 5.3 CORE PHASES (record examples see Chapter 2, section 2.6.2; Chapter 11, section 11.5.2, DS 11.3, EX 11.3 and animation files 5 and 6-10 via IS 11.3)

---

|         |                                                                                                                                                               |
|---------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|
| PKP     | (alt: P') unspecified P wave bottoming in the core                                                                                                            |
| PKPab   | (old: PKP2) P wave bottoming in the upper outer core; ab indicates the retrograde branch of the PKP caustic                                                   |
| PKPbc   | (old: PKP1) P wave bottoming in the lower outer core; bc indicates the prograde branch of the PKP caustic                                                     |
| PKPdf   | (alt: PKIKP) P wave bottoming in the inner core                                                                                                               |
| PKPpre  | (old: PKhKP) a precursor to PKPdf due to scattering near or at the CMB                                                                                        |
| PKPdif  | P wave diffracted at the inner core boundary (ICB) in the outer core                                                                                          |
| PKS     | Unspecified P wave bottoming in the core and converting to S at the CMB                                                                                       |
| PKSab   | PKS bottoming in the upper outer core                                                                                                                         |
| PKSbc   | PKS bottoming in the lower outer core                                                                                                                         |
| PKSdf   | PKS bottoming in the inner core                                                                                                                               |
| P'P'    | (alt: PKPPKP) Free-surface reflection of PKP                                                                                                                  |
| P'N     | (alt: PKPN) PKP reflected at the free surface N-1 times; N is a positive integer. For example P'3 is P'P'P'                                                   |
| P'z-P'  | PKP reflected from inner side of a discontinuity at depth z outside the core, which means it is precursory to P'P'; z may be a positive numerical value in km |
| P'S'    | (alt: PKPSKS) PKP converted to SKS when reflected from the free surface; other examples are P'PKS, P'SKP                                                      |
| PS'     | (alt: PSKS) P (leaving a source downward) to SKS reflection at the free surface                                                                               |
| PKKP    | Unspecified P wave reflected once from the inner side of the CMB                                                                                              |
| PKKPab  | PKKP bottoming in the upper outer core                                                                                                                        |
| PKKPbc  | PKKP bottoming in the lower outer core                                                                                                                        |
| PKKPdf  | PKKP bottoming in the inner core                                                                                                                              |
| PNKP    | P wave reflected N-1 times from inner side of the CMB; N is a positive integer                                                                                |
| PKKPpre | a precursor to PKKPdf due to scattering near the CMB                                                                                                          |
| PKiKP   | P wave reflected from the inner core boundary (ICB)                                                                                                           |
| PKNIKP  | P wave reflected N-1 times from the inner side of the ICB                                                                                                     |
| PKJKP   | P wave traversing the outer core as P and the inner core as S                                                                                                 |
| PKKS    | P wave reflected once from inner side of the CMB and converted to S at the CMB                                                                                |
| PKKSab  | PKKS bottoming in the upper outer core                                                                                                                        |
| PKKSbc  | PKKS bottoming in the lower outer core                                                                                                                        |
| PKKSdf  | PKKS bottoming in the inner core                                                                                                                              |
| PcPP'   | (alt: PcPPKP) PcP to PKP reflection at the free surface; other examples are PcPS', PcSP', PcSS', PcPSKP, PcSSKP                                               |
| SKS     | (alt: S') unspecified S wave traversing the core as P                                                                                                         |
| SKSac   | SKS bottoming in the outer core                                                                                                                               |
| SKSdf   | (alt: SKIKS) SKS bottoming in the inner core                                                                                                                  |
| SPdifKS | (alt: SKPdifS) SKS wave with a segment of mantle-side Pdif at the source and/or the receiver side of the ray path                                             |
| SKP     | Unspecified S wave traversing the core and then the mantle as P                                                                                               |
| SKPab   | SKP bottoming in the upper outer core                                                                                                                         |
| SKPbc   | SKP bottoming in the lower outer core                                                                                                                         |
| SKPdf   | SKP bottoming in the inner core                                                                                                                               |

|        |                                                                                                                                                               |
|--------|---------------------------------------------------------------------------------------------------------------------------------------------------------------|
| S'S'   | (alt: SKSSKS) Free-surface reflection of SKS                                                                                                                  |
| S'N    | SKS reflected at the free surface N-1 times; N is a positive integer                                                                                          |
| S'z-S' | SKS reflected from inner side of a discontinuity at depth z outside the core, which means it is precursory to S'S'; z may be a positive numerical value in km |
| S'P'   | (alt: SKSPKP) SKS converted to PKP when reflected from the free surface; other examples are S'SKP, S'PKS                                                      |
| S'P    | (alt: SKSP) SKS to P reflection at the free surface                                                                                                           |
| SKKS   | Unspecified S wave traversing the core as P with one reflection from inner side of the CMB                                                                    |
| SKKSac | SKKS bottoming in the outer core                                                                                                                              |
| SKKSdf | SKKS bottoming in the inner core                                                                                                                              |
| SNKS   | S wave traversing the core as P, reflected N-1 times from inner side of the CMB; N is a positive integer                                                      |
| SKiKS  | S wave traversing the outer core as P and reflected from the ICB                                                                                              |
| SKJKS  | S wave traversing the outer core as P and the inner core as S                                                                                                 |
| SKKP   | S wave traversing the core as P with one reflection from the inner side of the CMB and then continuing as P in the mantle                                     |
| SKKPab | SKKP bottoming in the upper outer core                                                                                                                        |
| SKKPbc | SKKP bottoming in the lower outer core                                                                                                                        |
| SKKPdf | SKKP bottoming in the inner core                                                                                                                              |
| ScSS'  | (alt: ScSSKS) ScS to SKS reflection at the free surface; other examples are ScPS', ScSP', ScPP', ScSSKP, ScPSKP                                               |

---

#### 5.4 NEAR SOURCE SURFACE REFLECTIONS (Depth phases); also see Figure 10 in Chapter 2, section 2.6.3, several examples in DS 11.2 and 11.3 and the animation files 4 and 6 in IS 11.3

---

|      |                                                                                                                                                                                                                                                                                                |
|------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| pPy  | All P-type onsets (Py) as defined above, which resulted from reflection of an upgoing P wave at the free surface or an ocean bottom; WARNING: The character "y" is only a wild card for any seismic phase, which could be generated at the free surface. Examples are: pP, pPKP, pPP, pPcP etc |
| sPy  | All Py resulting from reflection of an upgoing S wave at the free surface or an ocean bottom. For example: sP, sPKP, sPP, sPcP etc.                                                                                                                                                            |
| pSy  | All S-type onsets (Sy) as defined above, which resulted from reflection of an upgoing P wave at the free surface or an ocean bottom. For example: pS, pSKS, pSS, pScP, etc.                                                                                                                    |
| sSy  | All Sy resulting from reflection of an upgoing S wave at the free surface or an ocean bottom. For example: sSn, sSS, sScS, sSdif, etc.                                                                                                                                                         |
| pwPy | All Py resulting from reflection of an upgoing P wave at the ocean's free surface                                                                                                                                                                                                              |
| pmPy | All Py resulting from reflection of an upgoing P wave from the inner side of the Moho                                                                                                                                                                                                          |

## 5.5 SURFACE WAVES

|     |                                                                                                                                                                    |
|-----|--------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| L   | Unspecified long-period surface wave                                                                                                                               |
| LQ  | Love wave                                                                                                                                                          |
| LR  | Rayleigh wave                                                                                                                                                      |
| G   | Mantle wave of Love type                                                                                                                                           |
| GN  | Mantle wave of Love type; N is integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle     |
| R   | Mantle wave of Rayleigh type                                                                                                                                       |
| RN  | Mantle wave of Rayleigh type; N is integer and indicates wave packets traveling along the minor arcs (odd numbers) or major arc (even numbers) of the great circle |
| PL  | Fundamental leaking mode following P onsets generated by coupling of P energy into the waveguide formed by the crust and upper mantle                              |
| SPL | S wave coupling into the PL waveguide; other examples are SSPL, SSSPL                                                                                              |

## 5.6 ACOUSTIC PHASES

|     |                                                                                                                                                                                       |
|-----|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| H   | A hydroacoustic wave from a source in the water, which couples in the ground                                                                                                          |
| HPg | H phase converted to Pg at the receiver side                                                                                                                                          |
| HSg | H phase converted to Sg at the receiver side                                                                                                                                          |
| HRg | H phase converted to Rg at the receiver side                                                                                                                                          |
| I   | An atmospheric sound arrival, which couples in the ground                                                                                                                             |
| IPg | I phase converted to Pg at the receiver side                                                                                                                                          |
| ISg | I phase converted to Sg at the receiver side                                                                                                                                          |
| IRg | I phase converted to Rg at the receiver side                                                                                                                                          |
| T   | A tertiary wave. This is an acoustic wave from a source in the solid Earth, usually trapped in a low velocity oceanic water layer called the SOFAR channel (SOund Fixing And Ranging) |
| TPg | T phase converted to Pg at the receiver side                                                                                                                                          |
| TSg | T phase converted to Sg at the receiver side                                                                                                                                          |
| TRg | T phase converted to Rg at the receiver side                                                                                                                                          |

## 5.7 UNIDENTIFIED ARRIVALS

|    |                                                           |
|----|-----------------------------------------------------------|
| x  | (old: i, e, NULL) unidentified arrival                    |
| rx | (old: i, e, NULL) unidentified regional arrival           |
| tx | (old: i, e, NULL) unidentified teleseismic arrival        |
| Px | (old: i, e, NULL, (P), P?) unidentified arrival of P-type |
| Sx | (old: i, e, NULL, (S), S?) unidentified arrival of S-type |

## 5.8 AMPLITUDE MEASUREMENT PHASES

The following set of amplitude measurement names refers to the IASPEI (2013) Magnitude Standard, compliance to which is indicated by the presence of leading letter I. The absence of leading letter I indicates that a measurement is non-standard. Letter A indicates a measurement in nm made on a displacement seismogram, whereas letter V indicates a measurement in nm/s made on a velocity seismogram. All amplitude measurements for standard magnitudes, with the exception for ML, are made on vertical-component seismic records. For details on the measurement standards, e.g., on the required response simulation before measuring band-limited magnitudes like mb, mb(Lg), ML or Ms(20), the related measurements of periods, of the measurement time windows as well as on the relationship between standard and classical magnitudes see IS 3.3.

|         |                                                                                                                                                                             |
|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| IAML    | Displacement amplitude measured according to the IASPEI standard for local magnitude ML                                                                                     |
| IAMs_20 | Displacement amplitude measured according to IASPEI standard for surface-wave magnitude Ms(20)                                                                              |
| IVMs_BB | Velocity amplitude measured according to IASPEI standard for broadband surface-wave magnitude Ms(BB)                                                                        |
| IAmb    | Displacement amplitude measured according to IASPEI standard for short-period teleseismic body-wave magnitude mb                                                            |
| IVmB_BB | Velocity amplitude measured according to IASPEI standard for broadband teleseismic body-wave magnitude mB(BB)                                                               |
| IAmb_Lg | Displacement amplitude measured according to IASPEI standard for short-period Lg-wave magnitude mb(Lg)                                                                      |
| AX_IN   | Displacement amplitude of phase of type X (e.g., P, PP, S, etc.), measured on an instrument of type IN (wild card) (e.g., SP, short-period; LP, long-period; BB, broadband) |
| VX_IN   | Velocity amplitude of phase of type X and instrument of type IN (wild card as above)                                                                                        |
| A       | Unspecified displacement amplitude measurement                                                                                                                              |
| V       | Unspecified velocity amplitude measurement                                                                                                                                  |
| AML     | Displacement amplitude measurement for nonstandard local magnitude                                                                                                          |
| AMs     | Displacement amplitude measurement for nonstandard surface-wave magnitude                                                                                                   |
| Amb     | Displacement amplitude measurement for nonstandard short-period body-wave magnitude                                                                                         |
| AmB     | Displacement amplitude measurement for nonstandard medium to long-period body-wave magnitude                                                                                |
| END     | Time of visible end of record for duration magnitude                                                                                                                        |

| 3.2.4   | Magnitude scales for local and regional events                                                                                     | 59  |
| 3.2.4.1 | The original Richter magnitude scale ML                                                                                            | 60  |
| 3.2.4.2 | The new IASPEI standard ML                                                                                                         | 64  |
| 3.2.4.3 | Other Ml scales based on amplitude measurements                                                                                    | 65  |
| 3.2.4.4 | mb_Lg                                                                                                                              | 67  |
| 3.2.4.5 | Duration and coda magnitudes (Md and Mc)                                                                                           | 70  |
| 3.2.4.6 | The Russian K-class system for classifying earthquakes                                                                             | 75  |
| 3.2.4.7 | The Japanese $M_{JMA}$ scale                                                                                                       | 78  |
| 3.2.5   | Common teleseismic magnitude scales (P. Bormann and S. Wendt)                                                                      | 78  |
| 3.2.5.1 | Surface wave magnitude scales $M_s$ and the new IASPEI standards                                                                   | 80  |
|         | Question 1: Are the new IASPEI $M_s$ standards compatible with Gutenberg $M_s$ ?                                                   | 84  |
|         | Question 2: Is $M_s$ measured on horizontal and vertical components compatible?                                                    | 87  |
|         | Question 3: How reliably do the calibration formulas for $M_s$ determination compensate for the distance dependence of amplitudes? | 87  |
|         | Question 4: Why is there no depth term in the $M_s$ calibration functions?                                                         | 88  |
|         | Question 5: Are depth correction terms for $M_s$ available and feasible?                                                           | 89  |
|         | Question 6: How do travel paths affect the period at which $M_s_{BB}$ is measured?                                                 | 90  |
|         | Question 7: Why does the IASPEI $M_s$ formula not include a period dependence?                                                     | 92  |
|         | Question 8: Exist $M_s$ scales with a frequency-dependent calibration term?                                                        | 93  |
|         | Question 9: How do lateral velocity inhomogeneities affect the $M_s$ estimates?                                                    | 94  |
|         | Question 10: How do deviations from the standard instrument responses affect $M_s_{BB}$ and $M_s_{20}$ ?                           | 97  |
| 3.2.5.2 | Body-wave magnitude scales and the new IASPEI standards                                                                            | 97  |
|         | Question 1: Is modern $mB_B$ compatible with the classical Gutenberg $mB$ ?                                                        | 102 |
|         | Question 2: How relates standard $mb$ to $mb(NEIC)$ ?                                                                              | 103 |
|         | Question 3: How relate standard $mb$ and $mB_{BB}$ to each other?                                                                  | 105 |
|         | Question 4: How does the large scatter of period readings in $BB$ records affect the estimate of $mB_{BB}$ ?                       | 106 |
|         | Question 5: How do deviations from the standard responses affect $mb$ and $mB_{BB}$ ?                                              | 107 |
|         | Question 6: To what extent are differences between $mb$ and $mB_{BB}$ due to frequency-dependent attenuation?                      | 107 |
|         | Question 7: How reliable are the Gutenberg-Richter $Q(\Delta, h)_{PV}$ curves/tables?                                              | 108 |

### 3.1 Introduction to seismic sources and source parameters (P. Bormann)

*Seismic waves* (Chapter 2), generated by *seismic sources* (Chapter 3), are oscillations due to elastic deformations which propagate through the Earth and can be recorded by *seismic sensors* (Chapter 5) and *data acquisition systems* (Chapter 6). The *seismic moment* (section 3.1.2.3; IS 3.8, 3.10 and 3.11) and *seismic energy* (section 3.1.2.5; IS 3.6 and 3.9) released by these sources may cover a tremendous range of associated *magnitudes* (see 3.2) and thus can stir up a wide range of shaking *intensities* (Chapter 12) with potentially related damages. These and other source characterizing parameters, their mutual relationships as well as the

determination of seismic source mechanisms based on observation of polarity patterns and amplitude ratios between P and S waves as a function of azimuth are dealt with in detail in this chapter, related Information Sheets (IS) and Exercises (EX).

### 3.1.1 Types and peculiarities of seismic source processes

**Fig. 3.1** Schematic classification of various kinds of events which generate seismic waves. To the “classical” man-made events one should nowadays also add induced seismicity due to the injection of liquids into the underground and the extraction of hydrocarbons.

#### 3.1.1.1 Tectonic earthquakes

Tectonic earthquakes are caused when the brittle part of the Earth’s crust is subjected to stress that exceeds its breaking strength. Sudden rupture will occur, mostly along pre-existing faults but sometimes along newly formed faults. Rocks on each side of the rupture “snap” into a new position. For very large earthquakes, the length of the ruptured zone may be as much as 1000 km and the slip along the fault can reach several meters, sometimes even over a decameter.

Laboratory experiments show that homogeneous consolidated rocks under pressure and temperature conditions at the Earth’s surface will fracture at a volume strain on the order of  $10^{-2}$  -  $10^{-3}$  (i.e., about 0.1 % to 1% volume change) depending upon their porosity. Rock strength is generally smaller under tension or shear than under compression. Shear strains on the order of about  $10^{-4}$  or less may already cause fracturing of solid brittle rock. Rock strength is further reduced if the rock is pre-fractured, which is usually the case in continental Earth crust subjected to millions of years of still ongoing or previous phases of increased tectonic activity.

The strength of pre-fractured rock is much less than that of unbroken competent rock and is mainly controlled by the frictional resistance to motion of the two sides of the fault. Frictional resistance, which depends on the orientation of the faults with respect to the stress field and other conditions (see Scholz, 1990 and 2002), can vary over a wide range. Accordingly, deformations on the order of only  $10^{-5}$  to  $10^{-7}$ , which correspond to bending of a lithospheric plate by about 0.1 mm to 1 cm over a distance of 1 km, may cause shear faulting along pre-existing zones of weakness. But the shear strength depends also on the composition and fabric (anisotropy) of rock, its temperature, the confining pressure, the rate of deformation, etc. as well as the total cumulative strain. More details on the physics of earthquake faulting and related geological and seismotectonic conditions in the real Earth can be found in Scholz (1990 and 2002) and in section 3.1.4. Additional recommended overview articles on the rheology of the stratified lithosphere and its relation to crustal composition, age and heat flow were published by Meissner and Wever (1988), Ranalli and Murphy (1987) and Wever et al. (1987). They also explain the influence of these parameters on the thickness and maximum depth of the seismogenic zone in the Earth crust and lithosphere, i.e., the zone within which brittle fracturing of the rocks is possible when the strains exceed the breaking strength or elastic limit of the rock (see Chapter 2, Fig. 2.1).

Stress generated by the relative motions of lithospheric plates is the main cause of tectonic earthquakes. The plates are driven, pushed and pulled by the slow motion of convection currents in the more plastic hot material of the mantle beneath the lithosphere. These relative motions are in the order of several cm per year. Fig. 3.2 shows the global pattern of earthquake belts and the major tectonic plates. There are also numerous small plates called sub- or micro-plates. Shallow earthquakes, within the upper part of the crust, take place mainly at plate boundaries but may also occur inside plates (interplate and intraplate earthquakes, respectively). Intermediate (down to about 300 km) and deep earthquakes (down to a maximum of 700 km depth) occur under ocean trenches and related subduction zones where the lithosphere plates are thrust or pulled down into the upper mantle. The major trenches are found around the Circum-Pacific earthquake and volcanic belt (see Fig. 3.2). However, intermediate and deep earthquakes may occur also in some other marine or continental collision zones (e.g., the Tyrrhenian and Aegean Sea or the Carpathians and Hindu Kush, respectively).

Most earthquakes occur along the main plate boundaries. These boundaries constitute either zones of extension (e.g., in the up-welling zones of the mid-oceanic ridges or intra-plate rifts), transcurrent shear zones (e.g., the San Andreas fault in the west coast of North America or the North Anatolian fault in Turkey), or zones of plate collision (e.g., the Himalayan thrust front) or zones of subduction (mostly along deep sea trenches). Accordingly, tectonic earthquakes may be associated with many different faulting types (strike-slip, normal, reverse, thrust faulting or mixed; see text and Figures in 3.4.2).

The largest strain rates are observed near active plate boundaries (about  $10^{-8}$  to  $3 \times 10^{-10}$  per year). Strain rates are significantly less in active plate interiors (about  $5 \times 10^{-10}$  to  $3 \times 10^{-11}$  per year) or within stable continental platforms (about  $5 \times 10^{-11}$  to  $10^{-12}$  per year) (personal communication by Giardini, 1994). Consequently, the critical cumulative strain for the pre-fractured/faulted seismogenic zone of lithosphere, which is on the order of about  $10^{-6}$  to  $10^{-7}$ , is reached roughly after some 100, 1000 to 10,000 or 10,000 to 100,000 years of loading, respectively. This agrees well with estimates of the mean return period of the largest possible events (seismic cycles) in different plate environments (Muir-Wood, 1993; Scholz, 1990).

**Fig. 3.2** Global distribution of earthquake epicenters according to the data catalog of the United States National Earthquake Information Center (NEIC), January 1960 to November 2011, and the related major lithosphere plates. (Figure by courtesy of Regina Milkereit, GFZ German Research Centre for Geosciences).

Although there are hundreds of thousands of weak tectonic earthquakes globally every year, most of them can only be recorded by sensitive nearby instruments. But in the long-term global statistical average about 100,000 earthquakes are strong enough (magnitude  $M \geq 3$ ) to be potentially perceptible by humans in the near-source area. A few thousand are strong enough ( $M \geq 5$ ) to cause slight damage and some 100 with magnitude  $M > 6$  can cause heavy damage, if there are nearby settlements and built-up areas; while several events every year (with  $M \geq 8$ ) may result in wide-spread devastation and disaster. During the 20<sup>th</sup> century, the 1995 Great Hanshin/Kobe earthquake caused the greatest economic loss (about 100 billion US\$), the 1976 Tangshan earthquake inflicted the most terrible human loss (about 243,000 people killed) while the Chile earthquake of 1960 released the largest amount of *seismic energy*  $E_s$  of about  $5 \cdot 10^{18}$  to  $10^{19}$  Joule. The latter corresponds to about 25 to 100 years of the long-term annual average of global seismic energy release which is about  $1 - 2 \times 10^{17}$  J (Lay and Wallace, 1995) and to about half a year of the total kinetic energy contained in the global lithosphere plate motion. The total *seismic moment* (see 3.1.2.3. below) of the Chile earthquake was about  $3 \cdot 10^{23}$  Nm. It ruptured about 800 - 1000 km of the subduction zone interface at the Peru-Chile trench in a width of about 200 km (Boore, 1977; Scholz, 1990).

The commonly accepted *moment magnitude* value of  $M_w = 9.5$  has been published first by Kanamori and Cipar (1974). Considering also later papers, the ISC-GEM Global Instrumental Catalogue 1900-2009 (<http://www.isc.ac.uk/iscgem/>) adopted  $M_w = 9.6$  with a large uncertainty of  $\pm 0.3$  due to deficiency of the then seismic instrumentation and the complexity of this earthquake. According to Cifuentes and Silver (1989) this great Valdivia May 22<sup>nd</sup> 1960 Chile earthquake was in fact a multiple rupture, consisting of three events with a combined seismic moment of at least  $M_0 = 5.5 \times 10^{23}$  Nm, corresponding to  $M_w = 9.76$ , and an overall duration of about 1500 s. The faster rupturing main shock was preceded by a large scale slip with a rise time of 300 s and observable only at low frequencies, starting some 1150 s before the more high-frequency main shock initiated and another event that followed the main shock about 350 s later. When fully accounting for the probable very long-period energy release, associated with the long lasting slow rupture, which was not yet properly measurable with the 1960 available instrumentation, even  $M_w \approx 9.9$  might be conceivable. If this can be confirmed, then about 4 times more seismic energy than discussed above was released in this huge seismotectonic event.

In summary: about 85 % of the total world-wide seismic moment release by earthquakes occurs in subduction zones and more than 95 % by shallow earthquakes along plate boundaries. The other 5 % are distributed between intraplate events and deep and intermediate focus earthquakes. The single 1960 Chile earthquake accounts for about 25 % of the total seismic moment release between 1904 and 1986. And some of the devastating great earthquakes of the early 21<sup>st</sup> century were almost comparably large, such as the  $M_w 9.3$  Sumatra-Andaman earthquake of December 26, 2004 with a rupture duration of about 9 min, a rupture length of about 1300 km and with some 15 to 20 m fault slip, causing a tsunami with maximum run-up heights on land of almost 30 m locally, killing in total more than 230,000 people ([http://wikipedia.org/wiki/2004 Indian Ocean earthquake and tsunami](http://wikipedia.org/wiki/2004_Indian_Ocean_earthquake_and_tsunami); last accessed 03.07.2013).

It should be noted that most of the total energy released by seismic sources,  $E_T$ , e.g., the total available elastic strain energy, chemical, nuclear or other stored energy, is required to power the growth of the earthquake fracture, to produce frictional heat, sound or other. Only a small fraction of  $E_T$  goes into producing seismic waves. The seismic efficiency, i.e., the ratio of  $E_S/E_T$ , is usually only about 0.01 to 0.1. It depends both on the *stress drop* during the rupture as well as on the total stress in the source region (Spence, 1977; Scholz, 1990), the ambient medium and other factors (see sections 3.1.1.3 and 3.1.2.5).

### 3.1.1.2 Volcanic earthquakes

Although the total energy released by the strongest historically known volcanic eruptions was even larger than  $E_T$  of the Chile earthquake, the seismic efficiency of volcanic eruptions is generally much smaller, due to their long duration. Nevertheless, volcanic earthquakes of the tectonic type triggered by changes in the failure strength of the rock-fault system of the volcanic edifice or in its neighborhood due to volcanic processes, may in some cases locally reach the shaking strength of destructive earthquakes (e.g., with *magnitudes* of about 6). However, most of the seismic oscillations measured at volcanoes are of the tremor type and produced in conjunction with sub-surface magma flows. Tremors are long-lasting and more or less monochromatic oscillations which come from a two- or three-phase (liquid- and/or gas-solid) source process which is not narrowly localized in space and time. They cannot be analyzed in the traditional way of seismic recordings from tectonic earthquakes or explosions

nor be described with traditional source parameters (see Chapter 13). Such volcanic earthquakes contribute only an insignificant amount to the global seismic moment release (see Scholz, 1990). However, perturbations of the regional stress field by magmatic processes associated with an eruption or its preparation may also trigger tectonic earthquakes in the wider surroundings as part of the overall volcanic episode.

Explosions are mostly anthropogenic, i.e., “man-made”, and controlled, i.e., with known location and source time. However, strong natural explosions in conjunction with volcanic eruptions or meteorite impacts, such as the Tunguska meteorite of 30 June 1908 in Siberia or the Chelyabinsk/Ural meteorite impact on 15 February 2013 (see seismic records in Fig. 3.3a), may also occur.

**Fig. 3.3a** Seismic records of the Chelyabinsk/Ural meteorite impact of February 15, 2013, compiled at the GFZ German Research Centre for Geosciences (GFZ).

$10^{-3}$ , i.e., only 1 % to 0.1 % of the total released explosion energy is transformed into seismic energy). By means of decoupling techniques  $\varepsilon$  may be reduced by 2 to 5 orders (Adams and Allen, 1961; Adams and Swift, 1961; Latter et al., 1961a and b; Willies and Wilson, 1962). The coupling factor of explosions on the surface or in the atmosphere is much less ( $\varepsilon \approx 10^{-3}$  to  $10^{-6}$  depending on the altitude) and in the hydrosphere much larger ( $\varepsilon \approx 10^{-1}$ ) (see compilation of  $\varepsilon$  values in Bormann, 1966; or Båth, 1962; Griggs and Press, 1961; Pasečnik et al., 1960; Pomeroy and Oliver, 1960; Willies, 1963).

Explosions are expected to produce an outward directed compressional first motion in all directions while tectonic earthquakes produce first motions of different amplitude and polarity in different directions (Fig. 3.3b). These characteristics can be used to identify the type of source process (see 3.4) and to discriminate between explosions and tectonic earthquakes.

Compared to tectonic earthquakes, the *duration* of the source process of explosions and the *rise time* to the maximum level of displacement is much shorter (milliseconds as compared to seconds up to a few minutes) and more impulsive (Fig. 3.4). Accordingly, explosions of comparable body-wave magnitude excite more high-frequency oscillations and source spectra with about one order higher corner frequencies than average earthquakes having the same level of low-frequency energy (see Fig. 3.5).

**Fig. 3.3b** Schematic sketches of an idealized underground explosion and of a strike-slip earthquake along a vertically dipping fault. The fault motion is "left-lateral", i.e., counter-clockwise. The arrows show the directions of compressional (outward, polarity +, red shaded) and dilatational (inward, polarity -, green shaded) motions. The patterns shown on the surface, termed amplitude or polarity patterns, indicate the azimuthal variation of observed amplitudes or of the direction of first motions in seismic records (UP = + or DOWN = -), respectively. While point-like explosions in an isotropic medium should show no azimuth-dependent amplitudes and compressional first motions only, amplitudes and polarities vary for a tectonic earthquake. The dotted amplitude lobes in Fig. 3.3, right side, indicate qualitatively the different azimuth dependence of shear (S) waves as compared to longitudinal (P) waves (rotated by  $45^\circ$ ) but their absolute displacement amplitudes are – on average – about 5 times larger than those of P waves.

Rock falls may last for several minutes and cause seismic waves but generally with less distinct onsets and less separation of wave groups than tectonic earthquakes. The collapse of karst caves, mining-induced rock bursts or collapses of mining galleries are generally of an *implosion* type. Accordingly, their first motion patterns should show dilatations in all azimuths if a secondary tectonic event has not been triggered by the collapse. The strongest events may reach magnitudes up to about  $M = 5.5$  and be recorded world-wide (e.g., Bormann et al., 1992).

Besides this there are several other classes of induced and triggered seismicity. McGarr et al., (2002) summarize the case histories of several distinct stimulated seismic events and their causes, mainly due to changes in the ambient stress and/or pore pressure conditions in response to either other earthquakes in the surroundings or due to human activities. We shortly refer to 4 main types of such events which are:

- *reservoir induced earthquakes* which have frequently been observed in conjunction with the impoundment of water or rapid water level changes behind large dams. These events are triggered along pre-existing and pre-stressed tectonic faults, and they show the typical polarity patterns of tectonic earthquakes. The strongest event reported so far, the Koyna, India, earthquake of 1967 (Gupta and Rastogi, 1976) reached a magnitude of 6.5.
- *earthquakes induced by the injection of fluids* into a tectonically stressed crust. An interesting case is described by Horton (2012). Due to the disposal of hydrofracturing waste fluid, injected into aquifers at several hundred meters down to more than 3 km depth in Central Arkansas, an earthquake swarm was triggered in the surroundings of a major fault which has the potential to release a damaging earthquake.
- *earthquakes induced by hydrocarbon withdrawal* from the underground. Grasso and Wittlinger (1990) describe the result of 10 years monitoring of a gas field in France which has been seismically completely inactive prior to the gas extraction. Within the first 10 production years some 800 earthquakes with magnitudes ranging between 1.0 and 4.2 have been recorded. Pennington et al. (1986) relate to the pronounced depressuring of fault planes in oil and gas fields in Texas, where fluid pressures had dropped to less than 20% of their original values, producing earthquakes up to magnitude 3.9. For three more  $M \approx 6$  earthquakes in California, which occurred all directly over major fields of oil extraction (Coalinga, 1983; Kettleman North Dome, 1985; Whittier Narrows, 1987) it is suspected that they all have been induced by oil extraction over a still growing anticline (McGarr, 1991), although the focal depth of these events was some 8 km deeper. However, the ratio of net liquid production to total seismic moment released by all three events was nearly the same, as was the epicentral extension of the aftershock sequences of all three earthquakes which approximately coincided with the extension of the overlying oil fields. Similarly, the sequence of three  $M = 7$  earthquakes in April and Mai 1976 and in March 1984 in the Gazli region of Uzbekistan, with no known history of so strong earthquakes before the exploitation of the enormous gas resources there, had also been interpreted by Simpson and Leith (1985) as being likely related to the gas extraction. This supposition has also been supported by McGarr (1991) but questioned by Bossu (1996), who estimated that the total extracted mass of gas was only about  $1/4^{\text{th}}$  of the mass of the water which subsequently infiltrated the void space in the gas field.
- *earthquakes induced by stress changes* in the surrounding rocks caused by creating the mined-out void, often connected with blasting activity. Several such cases have been described in the literature. An early one relates to the East Rand Proprietary gold

Mines (ERPM, McGarr et al., 1975), a very recent one to the Mponeng gold mine, (Kwiatek et al., 2010; Plenkers et al., 2010), both in South Africa. These events are usually rather small. In the first case, magnitudes between -1.5 and 2.5 had been recorded, with the much more sensitive local underground network in 3.5 km depth in the Mponeng mine even events with  $M_w$  between -4.4 and -1.3. Monitoring of such production induced seismicity is also part of a mining safety alarm system. Since the events are so small and so close to the sensors (within meters to several ten meters), the frequencies recorded with acoustic emission sensors (AE) are very high, ranging between about 0.7 kHz and 200 kHz, yet their records show distinct P and S phases (Fig. 3c).

**Fig. 3.3c** Uncorrected waveforms in 25-ms windows for induced seismic events of different frequency content recorded at 3.5 km depth in the Mponeng gold mine, South Africa.

**Yellow:** low-frequency event ( $< 1$  kHz); **Blue:** event with dominating frequencies between 1 kHz and 25 kHz; **Green:** High-frequency (HF1) event with  $f > 25$  kHz; **Red:** Highest-frequency (HF2) events with  $f > 40$  kHz. Copy of Figure 2A of Plenkers et al. (2010), *Seism. Res. Lett.*, vol. 81, no. 3, p. 470; © Seismological Society of America.

However, earthquakes induced by stress redistribution are not a phenomena restricted to the very local range of mines and as a consequence of human action. Also stress redistribution after a strong earthquake may trigger in the prolongation of its own fault system or at adjacent ones another rather strong earthquake, which might have taken, without the preceding one, much longer to reach the critical state of rupture initiation. A good example is the  $M_w 7.2$  Düzce, Turkey, earthquake of 12 November 1999. It followed the  $M_w 7.4$  Izmit earthquake of 16 August 1999 along a nearby branching extension of the North Anatolian fault segment.

**Fig. 3.4** Schematic diagrams of the different source functions of explosions (left) and earthquakes (right).  $P$  - pressure in the explosion cavity,  $D$  - fault displacement,  $t$  - time,  $t_0$  - origin time of the event,  $t_r$  - rise time of  $P$  or  $D$  to its maximum values,  $t_{rf}$  - rise time of fast rupture,  $t_{rs}$  - rise time of slow rupture; the step function in the right diagram would correspond to an earthquake with infinite velocity of crack propagation  $v_{cr}$ . Common rupture models assume  $v_{cr}$  to be about 0.6 to 0.9 times of the velocity of shear-wave propagation,  $v_s$  (e.g., Madariaga, 1976), yet for very slow *tsunami earthquakes* it may be as slow as about 0.2  $v_s$  (Kanamori and Brodsky, 2004; Venkataraman and Kanamori, 2004b). Note the different time-scales for explosions and earthquakes.

#### 3.1.1.4 Microseisms and seismic noise

Seismic signals produced by storms over oceans or large water basins (seas, lakes, reservoirs) as well as by wind action on topography, vegetation or built-up surface cover are called *microseisms*. In contrast, seismic signals due to human activities such as rotating or hammering machinery, traffic etc., are *cultural seismic noise*. Rushing waters or gas/steam (in rivers, water falls, dams, pipelines, geysers) may be additional sources of natural or anthropogenic *seismic noise*. They are neither well localized in space nor fixed to a defined *origin time*. Accordingly, they produce more or less permanent on-going non-coherent interfering signals of more or less random amplitude fluctuations in a very wide frequency range of about 16 octaves (from about 50 Hz to 1 mHz) which are often controlled in their intensity by the season (natural noise) or time of day (anthropogenic noise). Despite the large range of ambient noise displacement amplitudes (about 6 to 10 orders of magnitude; see Chapter 4, Fig. 4.3) they are generally much smaller than those of earthquakes and not felt by people.

Differences between signals from coherent seismic sources on the one hand and microseisms/seismic noise on the other hand are dealt with in more detail in Chapter 4, filter, processing and installation procedures for the improvement of the signal-to-noise ratio (SNR) in seismic records are discussed in Chapters 4 and 7 and the use of ambient noise for microzonation is discussed in Chapter 14.

### 3.1.2 Parameters which characterize size, strength and mechanism of seismic sources

#### 3.1.2.1 Macroseismic intensity

The effect of a seismic source may be characterized by its *macroseismic intensity*, **I**. Intensity describes the strength of shaking in terms of human perception, damage to buildings and other structures, as well as changes in the surrounding environment. **I** depends on the distance from the source and the soil conditions and is mostly classified according to macroseismic scales of 12 degrees (e.g., Wood and Newman, 1931; Medvedev, 1962; Stover and Coffman, 1993; Grünthal, 1998). Exceptions are, e.g., the 7 degrees scales of Japan (see Chapter 12) and of Taiwan (Wu et al., 2003). From an analysis of the areal distribution of felt reports and damage one can estimate the epicentral intensity **I**<sub>0</sub> in the source area as well as the source depth, *h* (e.g., Sponheuer, 1960). There exist empirical relationships between **I**<sub>0</sub> and other instrumentally determined measures of the earthquake size such as the *magnitude*, peak ground velocity (PGV) and peak ground acceleration (PGA). Although these relationships are rather noisy it has been found that the earthquake damage statistics is much closer correlated with the PGV than with PGA (Wu et al., 2003). And magnitude-wise **I** is best correlated with local magnitude *M*<sub>l</sub> and energy magnitude *M*<sub>e</sub>, provided that the effect of distance between the source and the site where **I** is observed, is accounted for. Because, for two earthquakes with a given *M*<sub>w</sub>, the earthquake with the lower *M*<sub>e</sub> and *M*<sub>l</sub> tends to have a larger source, so that there may be more locations situated very close to a causative fault. Also, very shallow earthquakes tend to have relatively low *M*<sub>e</sub>, yet they are often intensively destructive in the immediate epicentral area or along the outcropping fault trace. For more details on macroseismic effects see Chapter 12 and for a comprehensive summary Grünthal (2011).

#### 3.1.2.2 Magnitude and early relationships to seismic energy

*Magnitude* is a logarithmic measure of the size of an earthquake or explosion based on instrumental measurements. The magnitude concept was first proposed by Richter (1935). Magnitudes are commonly derived from ground motion amplitudes and periods or from *signal duration* measured on instrumental records. There is no *a priori* scale limitation to magnitudes as it exists for macroseismic intensity scales. The largest moment magnitude, *M*<sub>w</sub>, observed so far, was that of the Chile earthquake in 1960 (*M*<sub>w</sub> ≈ 9.5 according to Kanamori, 1977). Nowadays, highly sensitive instrumentation close to the sources may record local events with magnitude even smaller than zero (e.g., *M*<sub>w</sub> down to -4.4 for induced seismicity recorded close-up in gold mines, Kwiatek et al., 2010). According to Richter's original definition these magnitude values become negative. With empirical *energy-magnitude-relationships* the *seismic energy*, *E*<sub>s</sub>, radiated by the seismic source as seismic waves can be estimated. Common relationships are those given by Gutenberg and Richter (1954, 1956a, b; Richter, 1958) between *E*<sub>s</sub> and the surface-wave magnitude *M*<sub>s</sub> and the body-wave magnitude *m*<sub>B</sub>:  $\log E_s = 11.8 + 1.5 M_s$  and  $\log E_s = 5.8 + 2.4 m_B$ , respectively (when *E*<sub>s</sub> is given in erg; 1 erg = 10<sup>-7</sup> Joule). According to these relationship, a change of *M*<sub>s</sub> or *m*<sub>B</sub> by one unit corresponds to a change in *E*<sub>s</sub> by a factor of about 32 times or 250 times, respectively.

Based on the analysis of digital recordings, there exist also direct procedures to estimate *E*<sub>s</sub> (e.g., Purcaru and Berckhemer, 1978; Seidl and Berckhemer, 1982; Boatwright and Choy, 1986; Kanamori et al., 1993; Choy and Boatwright, 1995) and to define an "energy

magnitude"  $M_e$  (see section 3.2.7.2). Because most of the seismic energy is concentrated in the higher frequencies around the *corner frequency*  $f_c$  of the radiated spectrum (see next section),  $M_e$  is a very suitable measure of the earthquakes' potential for damage. In contrast, the seismic moment, which is estimated from the displacement amplitude plateau at frequencies  $f \gg f_c$ ,  $M_0$  is related to the final static displacement after an earthquake and consequently, the moment magnitude,  $M_w$ , is more closely related to the tectonic effects of an earthquake (see Choy and Kirby, 2004; Di Giacomo et al., 2010; Bormann and Di Giacomo, 2011; IS 3.5).

### 3.1.2.3 Scalar seismic and geometric moment, source spectrum, source dimension and stress drop in relation to magnitude

Above we have already repeatedly referred to the terms *seismic moment* ( $M_0$ ) and *moment magnitude* ( $M_w$ ). The scalar *seismic moment*  $M_0$  (for its derivation see IS 3.1) is a measure of the "size" or "work" accomplished by a seismic shear source:

$$M_0 = \mu \bar{D} A \quad (3.1)$$

with  $\mu$  - rigidity or shear modulus of the source medium,  $\bar{D}$  - average final displacement after the rupture,  $A$  - the surface area of the rupture.  $M_0$  is a measure of the irreversible inelastic deformation in the rupture area. This inelastic strain is described in (3.1) by the product  $\bar{D} A$ . On the basis of reasonable average assumptions about  $\mu$  and the stress drop  $\Delta\sigma$  its determination is now standard in the routine analysis of strong earthquakes by means of waveform inversion of long-period digital records (see Dziewonski et al., 1981 and IS 3.8).

Although the scalar seismic moment provides a better physical quantification of the earthquake source than magnitude it is not directly measurable, since according to Ben-Zion (1989 and 2001) linear elastic waves generated by a slip source have no information on material properties at the source region itself. Only the product  $P = \bar{D} A$ , termed "geometric moment" by King (1978) or "potency  $P$ " by Ben-Menahem and Singh (1981), can be determined directly from the zero spectral asymptote of the source in a seismogram, respectively by integrating over the area underneath the restituted broadband displacement  $P$  and/or  $S$  waveforms recorded in the far-field of the source (e.g., Seidl and Berckhemer, 1982; Seidl and Hellweg (1988; see, e.g., Figs. 3.9, 3.63, 3.65a). The values for the rigidity  $\mu$ , however, has to be *assumed*. And different authors may assume in their moment calculations different values, e.g., when estimating  $M_0$  for earthquakes in very different seismotectonic environments and at very different source depths in the crust or upper mantle, in continental or oceanic areas. Then earthquakes of volumetrically equal size or potency have different seismic moment. Therefore, Ben-Zion (2001) recommends to convert reported moments to potencies by removing the assumed rigidities in order to make earthquakes sizes geometrically, respectively volumetrically comparable. In practice, however this often meets the difficulty that the rigidities assumed in the calculation of  $M_0$  are often not formally recorded. However, for southern California earthquakes with  $1.0 < M_l < 7.0$ , Ben-Zion and Zhu (2002) demonstrated a proper potency-magnitude scaling.

In a homogeneous half-space  $M_0$  can be determined from the spectra of seismic waves observed at the Earth's surface by using the relationship:

$$M_0 = 4\pi d \rho v_{p,s}^3 u_0 / R_{\theta,\phi}^{p,s} \quad (3.2)$$

with:  $d$  - hypocentral distance between the event and the seismic station;  $\rho$  - average density of the rock and  $v_{p,s}$  - velocity of the P or S waves around the source;  $R_{\theta,\phi}^{p,s}$  - a factor correcting the observed seismic amplitudes for the influence of the radiation pattern of the seismic source, which is different for P and S waves (see Figs. 3.3 and 3.100-3.103),  $u_0$  - the low-frequency level of displacement amplitudes as derived from the seismic spectrum of P or S waves, corrected for the instrument response, wave attenuation and surface amplification. For details see EX 3.4.

According to Aki (1967) a simple seismic shear source with linear rupture propagation shows in the far-field smooth displacement and velocity spectra. When corrected for the effects of geometrical spreading and attenuation we get "source spectra" similar to the generalized ones shown in Fig. 3.5. There the displacement spectral amplitudes have been scaled to the scalar seismic moment  $M_0$  (left) and the related velocity amplitudes to moment rate  $dM_0/dt$  (right), respectively. Additionally shown are the bandwidth ranges for measuring the IASPEI standard body wave magnitudes  $mb$  and  $mb(BB)$  as well as the standard surface-wave magnitudes  $Ms(20)$  and  $Ms(BB)$  (see IS 3.3). The spectral curves (solid lines) have been calculated on the basis of an  $\omega^{-2}$  source model (Aki, 1967) in which the moment rate function can be expressed as  $\hat{M}(f) = (M_0 f_c^2) / (f^2 + f_c^2)$  (Houston and Kanamori, 1986; Polet and Kanamori, 2000) with the corner frequency  $f_c = c\beta(\Delta\sigma/M_0)^{1/3}$  (Brune, 1970, 1971),  $\beta$  the shear-wave velocity near the source (assumed to be 3.75 km/s),  $c = 0.49$  and  $\Delta\sigma$  the stress drop in the source.  $\Delta\sigma$  has been assumed to be 3 MPa in agreement with Kanamori's (1977) condition  $E_s/M_0 = 5 \times 10^{-5}$ , on which the derivation of the  $M_w$ - $\log M_0$  relationship (Hanks and Kanamori, 1979) is based. According to this model the amplitudes decay is  $\sim f^{-2}$  for  $f \gg f_c$ . Although this "omega-squared" model is widely accepted as the best simple model of source spectra it is recognized that it does not adequately describe some source spectra. In real data, many kinds of departure from the  $f^{-2}$  decay law have been observed, with slopes ranging between about -1 and -5. Further, for earthquakes of a given seismic moment,  $\Delta\sigma$  may differ by about 3 orders of magnitude (e.g., Choy and Boatwright, 1995) and thus  $f_c$  according to the Brune relation by about a factor of 10. Moreover,  $f_c$  in P-wave and S-wave source spectra may differ. How much depends on the type of rupture model. If the corner frequency were determined entirely by source duration, then one would expect it to be independent on the wave type. According to Madariaga (1976), however, the corner-frequency is determined by the stopping phase from the sides of the fault nearest to and farthest from the observer. If this is true then the corner frequencies depend on the wave-type, but also vary with the position of the observer with respect to the source rupture and its radiation pattern. According to Table 2 and Eq. (3) in EX 3.4 it holds on average that  $f_c$  for P-waves is about 1.4 to 1.5 times larger than  $f_c$  for S-waves in the case of circular ruptures assumed by the Brune, respectively Madariaga models.

Before discussing the inferences one can draw from *seismic scaling laws*, respectively *source spectra* corrected for propagation effects (geometric spreading and attenuation), such as the ones in Fig. 3.5, we should make clear that details of theoretical "source spectra" depend on the model assumptions of the rupture process. E.g., when the rupture is bilateral, as in the Aki (1967)  $\omega^{-2}$  source model, the displacement spectrum of the source-time function drops for  $f \gg f_c$  proportional to  $f^{-2}$ , as in Fig. 3.5. In contrast, for an unilateral rupture (Haskell, 1964, 1966), the high-frequency decay is proportional to  $f^{-3}$  ( $\omega^{-3}$  model). The high-frequency drop-

off of real spectra typically ranges between about -1 and -3 (e.g., Hartzel and Heaton, 1985; Boatwright and Choy, 1989; Polet and Kanamori, 2000; IS 3.4), depending also on the specific source-time function. But even steeper decays have been observed. On the other hand, when the linear dimensions of the fault rupture differ in length and width then two corner frequencies will occur. Whether the two or three corner frequencies are resolvable will depend on their separation along the spectral axis and the spectral signal-to-noise ratio. In contrast to the smooth theoretical spectral curves in Fig. 3.5 real spectra calculated from noisy records of limited duration and bandwidth from earthquakes with different source-time functions and fault geometries will show fluctuating spectral amplitudes, sometime more than one corner frequency or – more likely - a rather broad range of transition with different slopes from the displacement plateau to the final drop-off. Therefore, real source spectra may not be well matched by such a smooth “average”  $\omega^{-2}$  source model and not allow to discriminate between different types of rupture propagation and source geometry. Nevertheless, Fig. 3.5 allows us to discuss essential differences and required bandwidth ranges for reasonably reliable measurements of  $M_0$  and  $E_S$ , of the related magnitudes  $M_w$  and  $M_e$  or complementary ones, as well as of the derivation of other source parameters of interest.

**Fig. 3.5 Left:** "Source spectra" of ground displacement amplitudes  $A$  as a function of frequency  $f$  for "average" seismic shear sources assuming the  $\omega^{-2}$  source model and constant stress drop of  $\Delta\sigma = 3$  MPa, scaled to seismic moment  $M_0$  and the equivalent moment magnitude  $M_w$ . **Right:** The same as left, but for ground motion velocity amplitudes  $V$ , scaled to seismic moment rate and  $M_w$ . Note that the maximum of seismic energy  $E_S \sim V^2$  is radiated around  $f_c$ . The open arrows point to the center frequencies on the abscissa at which the 1 Hz body-wave magnitude  $m_b$  and the 20 sec surface-wave magnitude  $M_s(20)$ , respectively, are determined. The horizontal interval bars mark the range of frequencies within which the maximum Sg/Lg-, P-wave and Rayleigh-wave amplitudes for ML, mB(BB) and Ms(BB) should be measured. For procedure of calculation see text (courtesy of Domenico

Di Giacomo, 2008). Modified version of Figure 1 in Bormann et al. (2009, BSSA, Vol. 99, No. 3, p. 1870); © granted by the Seismological Society of America.

With reference to Fig. 3.5, we ask and answer now the following questions:

- What does the shape of the spectra in Fig. 3.5 tell us about the source process?
- Which parameters should accordingly be measured?
- How do they relate to the size, shape, slip and stress drop in the seismic source?
- How do these parameter influence the measurement of magnitudes in different spectral ranges?

The following general features are obvious from Fig. 3.5:

- "Source spectra" are characterized by a "plateau" of constant displacement for frequencies smaller than the "corner frequency"  $f_c$  which is inversely proportional to the source dimension, i.e.,  $f_c \sim 1/L$ .
- The decay of spectral displacement amplitude beyond  $f > f_c$  is on average approximately proportional to  $f^{-2}$ .
- The plateau amplitude increases with seismic moment  $M_0$  and magnitude, while at the same time  $f_c$  decreases in the case of the validity of the  $\omega^{-2}$  model proportional to  $M_0^{-3}$  (see Aki, 1967).
- Magnitude estimates of earthquake size are closely related to seismic moment  $M_0$ , if the displacement amplitudes are sampled at frequencies smaller than the corner frequency  $f_c$  of the source spectrum, i.e., on or near to the low-frequency asymptote plateau of the source spectrum. This can be expected for  $m_b$  only at moment magnitudes  $M_w < 5.5$  and for  $M_s(20)$  at  $M_w < 8$ . For larger earthquakes, however, these magnitudes are likely to have numerical values less than  $M_w$ ,  $m_b$  much more than  $M_s(20)$ . In contrast,  $mB(BB)$  and  $M_s(BB)$  are measured in a wider range of periods resulting in reduced differences to  $M_w$  in certain magnitude ranges. These general rough estimates are supported by empirical data of the average differences between  $m_b$ ,  $mB$ ,  $M_s$  and  $M_w$  (see section 3.2.5).
- Since wave energy is proportional to the square of ground motion particle velocity, i.e.,  $E_s \sim (2\pi f u)^2 = (\omega u(\omega))^2$ , its maximum occurs at  $f_c$ . Therefore, for magnitudes to be a good measure of the amount of released seismic energy and thus of the earthquake strength in terms of ground-shaking and damage potential,  $V_{max}$  and the related period should be measured at or near to  $f_c$ .
- This is in agreement with the  $\log(A/T)_{max}$  input into the classical teleseismic magnitude formulas (see DS 3.1 and sections 3.2.5.11 and 3.2.5.2), provided that no a priori limits for the period range are imposed. The latter, however, is the case for  $m_b$  and  $M_s(20)$ , which sample  $V_{max}$  only in very limited ranges of frequency, not, however,  $mB(BB)$  and  $M_s(BB)$ , which cover the average maxima of the released velocity spectra reasonably well in the magnitude ranges 4 to 8 and 5.5 to 8.5, respectively.
- Good estimates of energy magnitude  $M_e$  require to integrate squared velocity source spectra sufficiently wide towards both sides of the spectral velocity peak (see Fig. 3.5, section 3.2.7.2 and Bormann and Di Giacomo, 2011).

- measuring displacement amplitudes at  $f > f_c$  or velocity amplitudes at  $f < \text{or} > f_c$  results in systematic underestimation of either moment or energy related magnitudes, the more the larger the frequencies differ from  $f_c$ .

**Note:** There have been objections against a preference for broadband magnitudes from those in favour of continuing to measure as classical teleseismic magnitudes only mb and Ms(20). They claim that one should be able, by **assuming** the same omega-squared model and no bias in the magnitude measurement, to estimate energy comparably well also from mb or Ms(20). But, in contrast to estimates based on direct broadband  $V_{\max}$  measurements, such estimates are even more model dependent. Measuring  $V_{\max}$  directly eliminates the influence of measurement errors in period, which is required for mb and Ms(20) calculations. Such errors may become rather large if displacement amplitudes are measured on the spectral slope which may for individual earthquakes significantly differ from the assumed omega-squared model. Moreover, also the ground displacement amplitudes calculated via measurements on narrowband filtered records are particularly sensitive to measurement errors if the period of the recorded  $A_{\max}$  falls into the period range of the steep slopes of the record transfer functions (see Fig. 3.16). Furthermore, nobody can tell for sure, without additional measurements at other record positions whether  $(A_{\max}/T)$  really corresponds to  $(A/T)_{\max}$  on the given record and how the latter relates to the true  $V_{\max}$  at a rather different period of the broadband ground motion spectrum at the given site. Therefore, only by hypothesis free direct measurement of  $V_{\max}$  one can expect to get the least biased (although also not error free) estimate of the actually released seismic energy.

The effect of underestimating the magnitude and thus the (dimensional) *size* or (potential shaking) *strength* of the earthquake is often misleadingly termed *magnitude saturation*. More correct would be to speak of a systematic underestimation of a magnitude with respect to a true non-saturating moment or energy related reference magnitude which grows linearly and everywhere with the same slope proportional with  $\log M_0$  or  $\log E_s$ , respectively. The underestimation of a non-reference magnitude is then due to the slower increase of its related measurement amplitudes with growing Mw or Me when they are measured at frequencies outside the displacement plateau or the velocity maximum, respectively. In fact, any conventional magnitude that is measured at a constant period or in a narrow period range, such as Ml, mb, mb(Lg) or Ms\_20, features “saturation” as soon as the measured periods fall below the corner period of the radiated source spectrum or are much smaller than the rupture duration. Yet, for short, we continue to term this effect in the following as the *spectral component of magnitude “saturation”*.

The general shape of the displacement source spectrum in Fig. 3.5 can be understood as follows:

We know from optics that under a microscope no objects can be resolved which are smaller than the wavelength  $\lambda$  of the light with which it is observed. In this case the objects appear as a blurred point or dot. In order to resolve more details, electron microscopes are used which operate with much smaller wavelengths. The same holds in seismology. When observing a seismic source of radius  $r$  with wavelengths  $\lambda \gg r$  at a great distance, one can not derive any information about the details of the source process but only of its overall (integral) features, i.e., one “sees” a *point source*. Accordingly, spectral amplitudes with wavelengths  $\lambda \gg r$  are constant and form a spectral plateau (if source duration is neglected). On the other hand, wavelengths that have  $\lambda \ll r$  can resolve internal details of the rupture process. In the case of

an earthquake they correspond to smaller and smaller elements of the rupture processes or of the fault roughness (*asperities* and *barriers*). Therefore, their spectral amplitude contributions decay rapidly with size and thus related higher frequencies.

Accordingly, the corner frequency,  $f_c$ , marks a critical position in the spectrum which is obviously related to the size of the source. According to Brune (1970; 1971) and Madariaga (1976), both of whom modeled a circular fault, the corner frequency in the P- or S-wave spectrum, respectively, is  $f_{c\ p/s} = c_m v_{p,s} / \pi r$ . In contrast, assuming a rectangular fault, Haskell (1964) gives the relationship  $f_{c\ p/s} = c_m v_{p,s} / (L \times W)^{1/2}$  with  $L$  the length and  $W$  the width of the fault. The values  $c_m$  are model-dependent constants and thus different for circular and rectangular faults but even for different models of circular faults [see Table 2 and Eq. (3) in EX 3.4]. Accordingly, one may roughly define also a critical wavelength  $\lambda_c \approx v/f_c = c_m \pi r$  or  $\lambda_c \approx c_m (L \times W)^{1/2}$  beyond which the source can be “seen” as a *point source* only.

But real fault ruptures may have any other shape which can only be approximated roughly by either a circular fault (more likely for small earthquakes within the brittle fracturing seismogenic zone of the Earth crust) or by a rectangular fault of different *aspect ratio*  $L/W$ , which is growing with the magnitude of great earthquakes that rupture the whole width (depth range) of the seismogenic zone and may, therefore, grow further only in  $L$  direction. This has consequences for seismic scaling laws for small and large earthquakes [see related discussions and controversies, e.g., Scholz (1982, 1994, 1997) and Wang and Ou (1998) with further related references].

Nevertheless, being aware of the model dependence and inherent uncertainties of seismic scaling laws such as the ones in Fig. 3.5, related rupture models and formulas as given, e.g. by Brune (1970, 1971) and Madariaga (1976), allow to roughly estimate the following source parameters by reading the following parameters from seismic source spectra that have been corrected for propagation effects (geometric spreading and attenuation):

- $M_0$  via Eq. (3.2) when measuring the displacement plateau amplitude  $u^0$  and accounting for the other parameters in that formula;
- Source radius  $R \sim 1 / 2\pi f_{cp/s}$ ;
- Area of the assumed circular rupture plane:  $A = \pi R^2$ ;
- Average dislocation  $\bar{D} = M_0 / (\mu A)$  by assuming a reasonable value for rigidity  $\mu = v_s^2 \rho$  in the source volume;
- Stress drop  $\Delta\sigma = (7/16)M_0 / R^3$  according to Eshelby (1957) and Keilis-Borok (1959).

Stress drop means the difference in acting stress at the source region before and after the earthquake. For more details see Figure 10 in IS 3.1. Note, however, that  $\Delta\sigma \sim R^{-3}$  and estimates of  $R$  not very reliable. Reasons are the relatively large reading errors in  $f_c$  plus the model-dependence of  $R$  (or other geometric parameter) estimates, which also depend on the assumed *rupture velocity*  $v_R$ . Therefore, stress-drop estimates maybe rather uncertain within about an order of magnitude. For more details see EX 3.4 with discussions.

#### 3.1.2.4 The influence of rupture velocity and duration on magnitude estimates

For reducing saturation, *rupture duration*, depending on rupture length and speed, has additionally to be taken into account, especially, when the largest amplitudes of non-dispersive of P-wave trains have to be measured. The average rupture duration  $T_{\text{Rav}}$  increases according to Bormann and Saul (2009a) with magnitude  $M$  according to

$$\log T_{\text{Rav}} \text{ (in s)} \approx 0.6 M - 2.8. \quad (3.3)$$

$M$  means in this relationship the largest measured magnitude, which is for  $M_w < 6$  usually the local magnitude  $M_l$  or  $m_b$  and for larger events  $M_s$  or  $M_w$ . Relationship (3.3) has been derived by using data published in Olson and Allen (2005) that are based on rupture velocity estimates in Somerville et al. (1999) and scaling relations between rupture length and magnitude published by Wells and Coppersmith (1994), complementing them by some direct rupture duration estimates of recent great earthquakes. This simple average relationship is easy to recall and yields with 0.5 magnitude units increase a doubling of  $T_{\text{Rav}}$ , e.g., for  $M = 6$  about 6 s, for  $M = 7$  about 25 s, for  $M = 8$  about 100 s, for  $M = 9$  about 400 s, and for  $M = 10$  about 1600 s. The figure for  $M = 9$  is close to respective estimates for the somewhat greater  $M_w 9.3$  Sumatra-Andaman earthquake of December 26, 2004 by Bormann and Wylegalla (2005), Krüger and Ohrnberger (2005), Gusev et al. (2007), Hara (2007), Bormann and Saul (2009b), and Lomax and Michelini (2009a and b, 2011). All these authors, with the exception of Gusev et al., describe procedures of non-saturating magnitude estimates in near real-time based on broadband P-wave data and take explicitly rupture duration into account. The  $M = 10$  figure of 1600 s agrees well with rupture durations given in Cifuentes and Silver (1989) for the “revised”  $M_w \approx 9.9$  of the great 1960 Chile earthquake (see discussion in 3.1.1.1).

Average estimates of  $T_{\text{Rav}}$  according to relationship (3.3) agree within a factor less than two with those that could be estimated from the corner frequencies  $f_c$  of the source spectra in Fig. 3.5 as a function of  $M_w$  when one assumes an average rupture velocity of about 2.5 km/s and that  $f_c$  is inversely proportional to  $T_{\text{Rav}}$ . For a given event magnitude, however, depending mainly on variations in stress drop (e.g., Choy and Boatwright, 1995) and rigidity in the source region (for *tsunami earthquakes* see., e.g., Houston, 1999; Polet and Kanamori, 2000), but other factors as well (see 3.1.2.5), true  $T_R$  may be a factor of 2 to 3 smaller or larger than  $T_{\text{Rav}}$  because of related differences in rupture velocity,  $v_R$ .  $v_R$  may range between about 0.2 and 0.9 times of the shear-wave velocity  $v_s$  (Venkataraman and Kanamori, 2004b), or even more than  $v_s$  if the hypothesis and still debated observations of supershear slip pulses with rupture velocities up to 5 km/s holds (e.g., Bouchon and Vallée, 2003). Fig. 3.6 shows an example of very large differences in rupture duration and thus duration of the P-wave trains radiated from events with equal  $M_w$ .

If the largest amplitude for magnitude determination is measured only within an a priori fixed limited measurement-time windows after the first body-wave onset that is shorter than the rupture duration, then the required **maximum** amplitude in the whole P-wave train may have been missed and thus  $m_b$  or  $m_B$  been underestimated. Since  $T_{\text{Rav}} > 6$  s for earthquakes with  $M > 6$ , it is likely that this is indeed the case for such earthquakes when  $A_{\text{max}}$  is measured within a time window  $< 6$  s, as it is common practice at the International Data Center (IDC) of the CTBTO (Comprehensive Test Ban Treaty Organization; see Chapter 15). We term this the *measurement time-window component* of saturation, which adds to the pronounced spectral saturation component of  $m_b$ . In combination, both component may indeed result in true saturation, as shown in Fig. 3.7 for  $m_b(\text{test})$ . In contrast, the new IASPEI

standard mb, which measures always the maximum amplitude within the whole P-wave train, including the range of depth phases, and ending (preferably) before the onset of PP is only reduced by the spectral component of saturation. Yet, standard mb keeps growing up to values of about 7.6 for the largest earthquakes with Mw around 9.

Compared with an earthquake of the same seismic moment or magnitude, the corner frequency  $f_c$  of a well contained underground nuclear explosion (UNE) in hard rock is about ten times larger. Accordingly, an UNE produces more high-frequent energy and thus has a larger  $E_s$  as compared with an earthquake of comparable mb. Accordingly, mb(IDC) does not underestimate mb even for the largest UNE but only for earthquakes with comparable seismic moment but much smaller corner frequency. Main cause of this difference in  $E_s$  and high-frequency content between UNE and earthquakes is that the source *duration* and thus the *rise time*,  $t_r$ , to the final level of static displacement is much shorter for explosions (see Fig. 3.4).

Moreover, the shock-wave front of an explosion, which causes the deformation and fracturing of the surrounding rocks and thus the generation of seismic waves, propagates with approximately the P-wave velocity  $v_p$  while the velocity of crack propagation along a shear fracture/fault is only about 0.5 to 0.9 of the S-wave velocity, i.e., about 0.3 to 0.5 times that of  $v_p$ . Additionally, the equivalent wave radiating surface area in the case of an explosion is a sphere with  $A = 4\pi r^2$  and not a plane with  $A = \pi r^2$ . Accordingly, for equal  $A$  the source radius  $R$  in the case of an explosion is smaller and thus the related corner frequency larger.

**Fig. 3.6** Velocity broadband records of earthquakes with practically identical Mw but very different rupture durations and therefore length of the P-wave trains. Record 2 and 3 are slow tsunami earthquakes. Grey shaded areas: Envelopes of high-frequency (1-3 Hz) filtered BB records. Estimated rupture durations range from about 25 s (record 1) to 190 s (record 3). The average TRav according to Eq. (3.3) for Mw = 7.7 would be 66 s. Figure copied from Figure 2 of Bormann and Saul Bormann et al. (2009, p. 700) with © granted by the Seismological Society of America.

**Fig. 3.7** Comparison of mb measured on WWSSN-SP filtered records a) within the first 6 s after the P-wave onset (mb test) and b) within the whole P-wave train according to the new IASPEI standard rules for mb measurement. For instrument response function and measurement rules see IS 3.3. While mb(test) saturates at about 6.4 (**red line**), with early underestimations beginning already at mb > 6, mb itself may grow up to about 7.6 for the greatest earthquakes (**blue line**). RXY = correlation coefficient, RMSO = orthogonal rms error. Figure compiled according to data in Bormann et al. (2009).

### 3.1.2.5 Factors which influence energy radiation and seismic efficiency

The ratio between radiated seismic energy and seismic moment,  $E_S/M_0$ , i.e., the seismic energy radiated per unit of moment release and termed “scaled energy” by Kanamori and Brodsky (2004), would remain constant if a seismic scaling law such as the one in Fig. 3.5, calculated for a specific rupture model with fixed stress drop and rupture velocity, would hold for all earthquakes. In fact, this was assumed by Kanamori (1977) and Hanks and Kanamori (1979) when they developed the moment magnitude scale  $M_w$  under the condition of

$$E_S/M_0 = 5 \times 10^{-5} = \text{constant}. \quad (3.4)$$

This, however, is not the case. According to Wyss and Brune (1968) holds

$$E_S/M_0 = \Delta\sigma/2\mu = \tau_a/\mu \quad (3.5)$$

with  $\tau_a$  = *apparent stress*, which can – with Eq. (3.1) - also be written as  $\tau_a = E_S/(D \cdot A)$ . Thus,  $\tau_a$  is equivalent to the seismic energy release per unit area of the ruptured surface  $A$  and per unit of slip. Since both  $\Delta\sigma$  and  $\mu$  may vary  $E_S/M_0$  is a useful parameter to characterize the dynamic properties of an earthquake (Aki, 1966; Wyss and Brune, 1968).

$\Delta\sigma$  and thus  $\tau_a$  may vary by about 3 to 4 orders of magnitude (e.g., Abercrombie, 1995; Choy and Boatwright, 1995). Accordingly, the difference between energy magnitude  $M_e$  and moment magnitude  $M_w$  may reach 1 m.u. and even more (e.g., Choy and Kirby, 2004; Di Giacomo et al., 2010a and b; Bormann and Di Giacomo, 2011; Figure 5 in IS 3.5).

In the case of tsunami earthquakes unusually low rigidity values  $\mu$  in the rupturing source volume, i.e., along near surface faults in shallow dipping subduction zones with water saturated ocean sediments (Houston, 1999; Polet and Kanamori, 2000 and 2009) may be the reason for their exceptionally slow ( $v_R \approx 0.2 v_s$ ) and unusually long lasting ruptures. The ratio  $E_S/M_0$  of *tsunami earthquakes* ranges between about  $2 \times 10^{-6}$  and almost  $10^{-7}$  and the related values of  $\Theta = \log E_S/M_0$  - termed “slowness parameter” by Okal and Talandier (1989) - between -5.7 and -7 (Lomax and Michelini, 2009a). Note that observed global average values of  $\Theta$  for earthquakes with magnitudes larger than 5.5 range between -4.7 and -4.9 (Choy and Boatwright, 1995; Choy et al., 2006; Weinstein and Okal, 2005), whereas the Kanamori (1977) condition in Eq. (3.4) corresponds to  $\Theta_K = -4.3$ .

According to Kanamori (1972) tsunami earthquakes are characterized by generating a much larger tsunami than it would be expected from their seismic moment. The reason is that according to Eq. (3.1) for a measured  $M_0$  the product  $\bar{D} \times A$  is strongly underestimated when instead of the much smaller real rigidity in the rupture area the much larger Kanamori (1977) value for average crust-upper mantle condition is assumed (Hirshorn and Weinstein, 2009). The latter, however, is routine in  $M_0$  calculations.

In this context we have to clarify that Kanamori (1977), when introducing the relationship

$$W = W_0 (= E_S) = (\Delta\sigma/2\mu) M_0 \quad (3.5)$$

based it on a simplified assumptions of the rupture process which did not account for the total energy balance. According to Kanamori and Brodsky (2004) the total change in potential energy  $W$  due to the rupture process has to be written as

$$\Delta W = E_S + E_G + E_H \quad (3.6)$$

with  $E_G$  = fracture energy and  $E_H$  = energy dissipated as heat due to kinematic friction on the fault and generated sound. Eq. (3.5), however, holds only when both  $E_G = E_H = 0$ , i.e., when neglecting both the fracture energy and the dissipated energy in the total energy budget. Yet, the radiated energy is less, at least (in the case with no dissipation)

$$E_S = (\Delta\sigma/2\mu) M_0 - E_G. \quad (3.7)$$

Husseini (1977) introduced the term of *radiation efficiency*, which for radiated seismic energy would read:

$$\eta_R = E_S/(E_S + E_G) \quad (3.8)$$

According to Kanamori (2006) this can also be written as

$$\eta_R = (2\mu/\Delta\sigma) (E_S/M_0). \quad (3.9)$$

Yet, then it becomes clear that  $E_S = (\Delta\sigma/2\mu) M_0$  holds only for  $\eta_R = 1$ , i.e., when all energy available for strain release is converted into seismic wave energy, and no energy  $E_G$  is dissipated during fracturing. This, however, is not the case.  $\eta_R$  ranges between about 0.02 and (by definition)  $<1$ . For some earthquakes, however,  $\eta_{R\eta} > 1$  were computed, either due to incorrect data correction, model inaccuracies or even real supershear slip-pulses (Bouchon and Vallée, 2003; Venkataraman and Kanamori, 2004b).

Moreover, it has to be made clear that radiation efficiency according to Eq. (3.8) should not be mistaken as the better known seismic efficiency, which additionally accounts for energy dissipation losses due to frictional heat and sound,  $E_H$ , i.e.,

$$\eta = E_S / (E_S + E_G + E_H). \quad (3.10a)$$

Thus, seismic efficiency, defined as the proportion of the total available strain energy which is radiated as seismic waves, may be significantly smaller than  $\eta_R$  the more so the larger  $E_H$ , and  $\eta_R$  could also be called the maximum seismic efficiency of ruptures with negligible dissipation. According to Kanamori (2001) slow ruptures are suggestive of a dissipative process. He gives for longitudinal shear (mode III) cracks the following relationship between  $\eta$ , rupture velocity  $v_R$  and shear-wave velocity  $v_s$ :

$$\eta = 1 - [(v_s - v_R)/(v_s + v_R)]^{1/2}. \quad (3.10b)$$

According to (3.10b) a rupture with  $v_R = 0.2 v_s$  would thus have a value of  $\eta = 0.18$  only. Other crack geometries, however, may yield other values.

In the above discussion we have focussed on the influence of variations in stress drop, respectively of  $\Delta\sigma/\mu$  on the ratio  $E_S/M_0$ , although we mentioned already related velocity variations. According to Newman and Okal (1998), even in the case of a kinematically simple rupture model this ratio is controlled by five dimensionless factors, namely the ratios (with different exponent) between (1) S- versus P-wave velocity to the fifth power, (2) rupture length versus rupture duration and Rayleigh-wave speed to the third power, (3) rupture velocity  $v_R$  versus shear-wave velocity  $v_s$  to the third power, (4) the aspect ratio rupture width versus rupture length to the second power, and (5) fault slip versus rupture width. The first factor is, for most rise and fall times of the source time function and for a Poissonian solid a constant. The second factor, however, depends on the *directivity* of the rupture which will be 1 for unilateral rupture but may increase up to 8 for a symmetric bilateral rupture. However, Venkataraman and Kanamori (2004a) showed for a suite of earthquakes that the directivity corrections were less than a factor three and for dip-slip earthquakes with rupture propagation along strike even less than two at teleseismic distances. The third factor expresses the slowness of rupture, which may vary between about 0.5 for a “regular” ratio  $v_R/v_s \approx 0.8$  and about 0.01 and 0.03 for very slow earthquake ruptures with  $v_R/v_s \approx 0.2-0.3$  and  $v_R \approx 1$  km/s, slowed down by subducted sedimentary material along the fault zone (Kikuchi and Kanamori, 1995). The fourth factor, the squared aspect ratio, might be around  $1/4$  for most rupture geometries, but could be significantly smaller for ribbon-like ruptures on strike-slip faults and in the case of great earthquakes which brake the whole brittle-fracturing seismogenic zone of the lithosphere and can then grow further only in strike direction. And the last factor depends on the geometry model of the source. Thus we see that a great many of factors, most of them not directly measurable, may influence the “scaled energy” or slowness parameter  $\Theta$  of individual earthquakes.

In an effort to reduce this complexity down to the most important factors one finds that according to Kostrov (1966) and Eshelby (1969) the radiation efficiency of transverse shear cracks is

$$\eta_R \approx (v_R/v_s)^2. \quad (3.11)$$

When inserting (3.11) into (3.9) and resolves it for the ratio  $E_S/M_0$  one gets according to Bormann and Di Giacomo (2011):

$$E_S/M_0 = \eta_R \cdot (\Delta\sigma/2\mu) \approx (v_R/v_s)^2 \cdot (\Delta\sigma/2\mu). \quad (3.12)$$

Although being model-dependent (and other models are likely to produce other relationships), Eq. (3.12) illustrates a trade-off between variations in stress drop, rigidity, rupture velocity and shear-wave velocity in controlling the ratio  $E_S/M_0$  and thus, the relationship between  $M_w$  and  $M_e$ . Since, however, stress-drop estimates, despite their principle uncertainty, show the largest variability with 3 to 4 orders of magnitude, most of the observed differences in scaled seismic energy released by individual earthquakes may be attributable to differences in stress drop, the more so, since  $\Delta\sigma/2\mu$  in the source volume seem to set the stage for  $v_R/v_s$ , i.e., the two terms in (3.12) are not fully independent.

Finally, one should note in this context that a thorough investigation by Oth et al. (2010) of 1,826 earthquakes with  $M(JMA)$  magnitudes (see Eq. 3.34) between 2.7 and 8 throughout Japan led to the conclusions that:

- the calculated source spectra can be well characterized by the omega-square model (i.e., as in Fig. 3.5);
- on average self-similar scaling over the entire magnitude range holds, with median stress drops of 1.1 and 9.2 MPa for crustal and subcrustal events, respectively;
- the **ratio**  $E_S/M_0$ , as theoretically expected if the omega-squared model is valid, does not depend on magnitude and that the observed large scatter is mainly related to the scatter in stress drop.

### 3.1.2.6 Parameters which describe and control the source mechanism

Assuming that the earthquake rupture occurs along a planar fault surface the orientation of this plane in space can be described by three angles: *strike*  $\phi$  ( $0^\circ$  to  $360^\circ$  clockwise from north), *dip*  $\delta$  ( $0^\circ$  to  $90^\circ$  against the horizontal) and the direction of slip on the fault by the *rake angle*  $\lambda$  ( $-180^\circ$  to  $+180^\circ$  against the horizontal). Figures 5 and 6 in exercise EX 3.2 define these angles and Figures 3 as well as the solution figures show how to determine them from a stereographic (Wulff) net or equal area (Lambert-Schmidt) projection using observations of first motion polarities. It can be shown that a rupture along a plane perpendicular to the fault plane and with a slip vector perpendicular to the slip on the first plane causes an identical angular distribution of first motions. Therefore, on the basis of first motion analysis alone one can not decide which of the two planes is the truly acting one. For more detailed discussion on this see section 2.4 in IS 1.1.

Note that in the case of a shear model the fault-plane solution (i.e., the information about the orientation of the fault plane and of the fault slip in space) forms, together with the information about the static seismic moment  $M_0$  (see 3.1.2.3), the seismic moment tensor  $M_{ij}$

(see Equation (25) in IS 3.1). The principal axes of the moment-tensor coincide with the direction of the pressure axis, P, and the tension axis, T, associated with fault-plane solutions. However, they should not be mistaken for the principal axes  $\sigma_1$ ,  $\sigma_2$  and  $\sigma_3$  (with  $\sigma_1 > \sigma_2 > \sigma_3$ ) of the acting stress field in the Earth which is described by the stress tensor. Only in the case of a fresh crack in a homogeneous isotropic medium in a whole space with no pre-existing faults or zones of weakness and vanishing internal friction is P in the direction of  $\sigma_1$  while T has the opposite sense of  $\sigma_3$ . P and T are perpendicular to each other and each one forms, under the above conditions, an angle of  $45^\circ$  with the two possible conjugate fault planes (*45°-hypothesis*) which are in this case perpendicular to each other (see Figs. 3.99-3.101, 3.106 and 3.111 in sections 3.4.1 and 3.4.2). The orientation of P and T is also described by two angles each: the *azimuth* and the *plunge*. They can be determined by knowing the respective angles of the fault plane (see EX 3.2). If the above model assumptions hold true, one can, knowing the orientation of P and T in space, roughly estimate the orientations of  $\sigma_1$  and  $\sigma_3$ . Most of the data used for compiling the global stress map (Zoback, 1992; Zoback and Zoback, 2002) come from earthquake fault-plane solutions interpreted under these assumptions.

In reality, the internal friction of rocks is not zero. For most rocks this results, according to Anderson's (1951) theory of faulting in the formation of conjugate pairs of faults which are oriented at about  $\pm 30^\circ$  to  $\sigma_1$ . In this case, the directions of P and T, as derived from fault-plane solutions, will not coincide with the principal stress directions. Moreover, near the surface of the Earth one of the principal stresses is almost always vertical. In the case of a horizontal compressive regime, the minimum stress  $\sigma_3$  is vertical while  $\sigma_1$  is horizontal. This results, when fresh faults are formed in unbroken rock, in thrust faults dipping about  $30^\circ$  and striking parallel or anti-parallel to  $\sigma_2$ . In an extensional environment,  $\sigma_1$  is vertical and the resulting dip of fresh normal faults is about  $60^\circ$ . When both  $\sigma_1$  and  $\sigma_3$  are horizontal, vertical strike-slip faults will develop, striking with  $\pm 30^\circ$  to  $\sigma_1$ . But most earthquakes are associated with the reactivation of pre-existing faults rather than occurring on fresh faults.

Since the frictional strength of faults is generally less than that of unbroken rock, faults may be reactivated at angles between  $\sigma_1$  and fault strike that are different from  $30^\circ$ . In a pre-faulted medium this tends to prevent breaking of a new fault. Accordingly, there is no straightforward way to infer from the P and T directions determined for an individual earthquake the directions of the acting principal stress. On the other hand, it is possible to infer the regional stress based on the analysis of many earthquakes in that region since the possible suite of rupture mechanisms activated by a given stress regime is constrained. This method aims at finding an orientation for  $\sigma_1$  and  $\sigma_3$  which is consistent with as many as possible of the actually observed fault-plane solutions (e.g., Gephart and Forsyth, 1984; Reches, 1987; Rivera, 1989).

### 3.1.3 Mathematical, physical and geological representation of earthquakes

It is beyond the scope of the NMSOP to dwell on the physical and geological models of seismic sources and their mathematical representation. There exists quite a number of good text books on these issues (e.g., Aki and Richards, 1980 and 2002; Ben-Menahem and Singh, 1981 and 2000; Das and Kostrov, 1988; Scholz, 1990 and 2002; Lay and Wallace, 1995; Udías, 1999) as well as review papers on the physics and dynamics of earthquakes (e.g., Madariaga and Olsen, 2002; Teisseyre and Majewski, 2002; Kanamori and Brodsky, 2004;

Madariaga, 2011), on earthquakes as a complex system (Turcotte and Malamud, 2002) and quite many on earthquake geology and mechanics in Lee et al. (2002).

However, many of these texts are rather elaborate and more research oriented. Therefore, we have added to this Manual a more concise introduction into the theory of source representation in IS 3.1. It outlines how the basic relationships used in practical applications of source parameter determinations have been derived, on what assumptions they are based and what their limitations are. We have also added some exercises (EX 3.2-3.4) based on very simplified model assumptions and try to give with the following short section at least some idea of earthquakes as complex activated fault systems in real Earth.

### **3.1.4 Empirical analysis of rupture geometry, kinematics and dynamics in space and time**

So far we have mainly considered simple earthquake models applied routinely in seismological practice to derive suitable parameters for describing the size and behavior of faulting of earthquakes and to some extent also of explosions. In reality, earthquakes do not rupture along perfect planes, nor are their rupture areas truly circular or rectangular. Rather they occur in inhomogeneous rock, rupture along mechanically heterogeneous planes, do not slip just unilaterally or bilaterally but in patterns that may be very complex both in time and space. Therefore, seismologically derived fault plane and rupture parameters are usually at best first order approximations or simplifications to the truth in order to make the problem mathematically and with limited data tractable. Real faults show jogs, steps, branching, splays, etc., both in their horizontal and vertical extent (Fig. 3.8). Such jogs and steps, depending on their severity, are impediments to smooth or ideal rupture, as are bumps or rough features along the contacting fault surfaces. More examples can be found in Scholz (1990 and 2002). Since these features exist at all scales, which implies the self-similarity of fracture and faulting processes and their fractal nature (Turcotte, 1997; Turcotte and Malamud, 2002), this will necessarily result in heterogeneous dynamic rupturing and finally also in rupture termination.

**Fig. 3.8** Several fault zones mapped at different scales and viewed approximately normal to slip (from Scholz, *The mechanics of earthquakes and faulting*, 1990, Fig. 3.6, p. 106; with permission of Cambridge University Press).

Fig. 3.9 illustrates the complexity of earthquake ruptures over time as a common feature. Each event, often occurring as a multiple rupture process, seems to have its own "moment-rate fingerprint". Only in recent decades dense strong-motion networks been fortuitously deployed in the very source region of a strong earthquake. Strong-motion data recorded on a common time-base enable a detailed analysis of the rupture history in space and time using the moment-rate density.

As an early example, Fig. 3.10 depicts an inversion of data by Mendez and Anderson (1991) for the rupture process of the 1985 Michoacán, Mexico earthquake. Shown are snapshots, 4 s apart from each other, of the dip-slip velocity field. The contours represent dip-slip velocity at 5 cm/s interval, the cross denotes the NEIC hypocenter. Three consecutively darker shadings are used to depict areas with dip-slip velocities in the range: 12 to 22, 22 to 32, and greater than 32 cm/s, respectively. Abbreviations used: t - snapshot time after the origin time of the event, h - depth, D - distance in strike direction of the fault. One recognizes two main clusters of maximum slip velocity being about 120 km and 30 s apart from each other. The related maximum cumulative displacement was more than 3 m in the first cluster and more than 4 m in the second cluster at about 55 km and 40 km distance down-dip from the top of the rupture, respectively. About 90 % of the total seismic moment was released within these two main clusters which had a rupture duration each of only 8 s while the total rupture lasted for about 56 s (Mendez and Anderson, 1991). Although the overall rupture of the 1985 Michoacán, Mexico, earthquake was unilateral, both segments of main moment release expanded also bilaterally both in strike and vertical direction.

**Fig. 3.9** Moment-rate (source time) functions for some large earthquakes in the 1960s and 1970s as obtained by Kikuchi and Fukao (1987) (modified from Fig. 9 in Kikuchi and Ishida, Source retrieval for deep local earthquakes with broadband records, *Bull. Seism. Soc. Am.*, Vol. 83, No. 6, p. 1868, 1993, © Seismological Society of America).

**Fig. 3.10** Snapshots of the development in space and time of the inferred rupture process of the 1985 Michoacán, Mexico, earthquake. See text for discussion (redrawn and modified from Mendez and Anderson, The temporal and spatial evolution of the 19 September 1985 Michoacán earthquake as inferred from near-source ground-motion records, *Bull. Seism. Soc. Am.*, Vol. 81, No. 3, Fig. 6, p. 857-858, 1991; © Seismological Society of America).

Realizing in Fig. 3.10 the very large differences in moment release over the total rupture area one really has to question the relevance for seismic hazard assessment of the average point source displacement in relationship (3.1) for the scalar seismic moment, but also of the concept of the low resolution overall “centroid” time (usually calculated at half-time of the source-time function) and of the related centroid epi- and hypocenter. Calculating the rupture velocity from the ratio of total rupture length  $L$  / total rupture duration  $T_R$ , average slip and/or stress drop would yield a misleading picture which by no means reflects the kinematic and dynamic complexity of such complex earthquakes. Gross (1996) referred to the fact that inversions of waveforms in large earthquakes have consistently shown that the spatial distribution of moment release in real earthquakes is very irregular and not at all like the smooth distribution that one would expect if the classical theory of homogeneous elastic solids according to Kanamori and Anderson (1975) would hold for all earthquakes. This led Koyama (1985) to develop a theory of incoherent fracture of random fault heterogeneities and to discuss from this perspective the physical basis of earthquake magnitudes and the relationships of  $M_s$  on the one hand and of the maximum short-period P-wave magnitude  $m_b^*$  on the other hand (Koyama and Zheng, 1985) with ruptured fault area.

Gross (1996) proposed other heterogeneous slip models. They have the advantage of not only accounting for heterogeneous slip of large earthquakes due to the breaking of major asperities but also of predicting complex sources for small events, i.e., earthquake ruptures with dimensions less than the thickness of the seismogenic zone of brittle fracturing. On the other hand, for small earthquakes, the Gross models resemble classical crack theory by yielding also the well established area scaling relationship between average slip  $S$  and rupture area  $A$ , which is  $S \propto \sqrt{A}$ .

The rupturing of local asperities produces most of the high-frequency content of earthquakes. Accordingly, they contribute more to the cumulative seismic energy release than to the moment release. This is particularly important for engineering seismological assessments of expected earthquake effects. Damage to (predominately low-rise) structures is mainly due to frequencies  $> 2$  Hz. They are grossly underestimated when analyzing strong earthquakes only on the basis of medium and long-period teleseismic records or when calculating model spectra assuming smooth (average point source) rupturing along big faults of large earthquakes.

First results of a detailed investigation of rupture propagation by means of a nearby linear accelerometer line to the Oct. 15, 1979  $M_s = 6.9$  ( $M_w = 6.4$ ) Imperial Valley, California, earthquake were published by Spudich and Cranswick (1984). They showed that the observed high-frequency ground motions (accelerations up to 1.9 g were measured during this earthquake!) originate at irregularly distributed regions on the fault surface or are due to variable rupture velocity or both.

Goldstein and Archuleta (published 1991) made first direct measurements of 2-D earthquake rupture propagation using the SMART 1 array in Taiwan. They showed that the Jan. 29, 1981  $M_l = 6.3$  Taiwan earthquake ruptured unilaterally up-dip and towards the west on a  $60^\circ$  dipping and  $109^\circ$  striking reverse fault. They calculated a fault length of  $25 \pm 18$  km and a rupture duration of  $T_R = 9.4 \pm 3.6$  s. The latter is in perfect agreement with formula (3.3) for average magnitude-dependent rupture duration. Similarly, the overall rupture duration of 35 s of the Nov. 14, 1986, the  $M_w = 7.3$  Hualien, Taiwan, earthquake, also agreed within 10 % with the 38 s expected according to formula (3.3), although its source-time function showed two distinct sub-events with the by far dominating first one breaking within some 12 s only

(see Fig. 3.11). Thus, these strong-motion data highlighted that realistic strong-motion modeling requires much more detailed information about the source process than long-period moment tensor point source solutions can provide. Moreover, a detailed analysis of teleseismic data allowed to prove for the Hualien earthquake a clear migration in both horizontal and vertical directions of the patches of main seismic moment release (Hwang and Kanamori, 1989; Fig. 3.11 below), thus confirming the complexity of the source process both in space and time.

**Fig. 3.11** Source-time function (top) and spatial and time migration of areas of main moment release (bottom) of the 1986  $M_w = 7.3$  Hualien earthquake, Taiwan according to Hwang and Kanamori (1989), derived from teleseismic observations. Circle radii are proportional to the released seismic moment, numbers in the middle of the circles give the time after origin time in seconds. (Copy of Fig. 12 in Goldstein and Archuleta, J. (1991), *Geophys. Res.*, 96, p. 6197; © with kind permission of American Geophysical Society).

After the devastating great 2004  $M_w 9.3$  Sumatra-Andaman earthquake Krüger and Ohrnberger (2005) used the large aperture (500 km by 700 km) German Regional Seismic Network (GRSN) as a broadband array to track the propagation of this some 1200 km long rupture from a distance of about 9000 km (Fig. 3.12). An animation or the rupture tracking can be viewed and downloaded from section 2.5 in IS 1.1.

**Fig. 3.12 Left:** Source area of the great 2004 Sumatra-Andaman earthquake and great circle paths of from the epicenter location to the German Regional Seismic Network. **Right:** Map of maxima of seismic energy released during the earthquake in space and time from below upward. Circle radii are proportional to released seismic energy, circle colors are coded to rupture time. (Compiled from Figures 1 and 3 of Krüger and Ohrnberger (2005), *Nature*, 435, p. 937 and 938; © granted with kind permission by Nature Publishing Group).

The following conclusions could be drawn from this teleseismic array rupture tracking:

- The propagating rupture front could be tracked over a total length of 1,150 km;
- The average rupture speed was estimated to be 2.3 – 2.7 km/s but with slightly higher velocity on the southern segment (2.4-2.8 km/s) as compared to the northern branch of the rupture (2.1-2.4 km/s);
- The total rupture duration was at least 430, probably between 480 and 500 s;
- During the first 60 s, the position of the energy maximum did not move, which hints to a phase of bilateral growth of the rupture surface, whereas the remaining rupture was unilateral towards the north, with a second center of major energy release about 600 km NNW of the epicenter, which developed some 300 s after rupture initiation;
- The rupture did not progress farther to the south-southeast at the beginning of the rupture. This may indicate that the rupture front hit a barrier in this direction, which broke, in fact three months later during the March 28, 2005,  $M_w = 8.5$  earthquake;
- The complete estimate of source extension by means of rupture tracking of such a great event could be made available within about 30 min when using teleseismic station networks or large aperture arrays.

It should be noted, however, that first rough estimates of several of these aspects of the rupture process as a function of time, such as rupture duration, rise time and identifying time segments of increased energy radiation could already be derived within about 10 to 15 min. after origin time by processing and plotting single station records according to the procedure described by Bormann and Saul (2009b) for a fully automatic determination of the cumulative body-wave magnitude  $mB_c$  (for details see section 3.2.8.1). Applied to a record of the great Sumatra-Andaman earthquake at epicentral distance of  $52.7^\circ$  (Fig. 3.13) one realizes that

- initial rupture episodes around 30 s and 100 s after rupture initiation correspond already to sub-event broadband body-wave magnitudes  $mB$  around 8;
- the second episode released by far most of the energy of the whole rupture process;
- other, although less pronounced, episodes around 300s and 400 s after rupture initiation resulted in similarly large sub-event  $mB$  values (up to 8.3);
- thus the source-time function of the earthquake was rather asymmetric and therefore could not be approximated well by a symmetric triangular moment-rate function as prescribed by the routine Harvard/GCMT moment tensor procedure;
- the latter point, together with the fact that the longest periods analyzed by the GCMT standard procedure were shorter than the overall rupture duration, explains the initial underestimation of  $M_w(\text{GCMT}) = 8.9$  and  $9.0$ , respectively, for this earthquake. This could only be corrected by a later offline multiple CMT source analysis, which approximated the source-time function by trapezoid source-time functions of 5 individual sources, yielding then an overall  $M_w = 9.3$  (Tsai et al., 2005);
- cumulative  $mB_c$  may yield the same value straight away as the asymptotic “saturation” value of the real-time development of  $mB_c$  as a function of time;
- the rupture duration can be estimated reasonably well from the average amplitude envelopes of several high-frequency (1-3Hz) filtered records, when they fall below 40% of their maximum amplitudes (corresponding to 16% of the maximum energy

release), even after the arrival of stronger but in high-frequency content depleted secondary arrivals after P (see also Kanamori and Helmberger, 2005);

- thus estimated rupture duration of 540 s for the Sumatra-Andaman earthquake estimate agrees well (within about 10%) with similar independent estimates (e.g., Lomax, 2005; Kanamori and Helmberger, 2005).
- 

**Fig. 3.13** Velocity-proportional recording of the great Sumatra-Andaman earthquake at station PMG, processed with the mBc procedure originally proposed by Bormann and Khalturin (1975) and developed as a fully automated procedure by Bormann and Saul (2009b). Blue bars correspond to mB values of major amplitude onsets according to the condition  $V_i \geq 0.6V_{\max,t}$  with  $V_{\max,t}$  being the maximum velocity amplitude up to the time  $t$ , with the largest single amplitude mB marked by a blue triangle. The red curve shows the development of mBc with time and the red triangle the mBc values reached prior to the onset of S. The grey shaded area marks the high-frequency P-wave envelop (courtesy of J. Saul, 2009)

With respect to source complexity and related energy radiation of this gigantic earthquake Kanamori (2006) added that the ratio  $E_s/M_0 = 4.6 \times 10^{-6}$  was slightly smaller than that for other large subduction-zone earthquakes and that the average radiation efficiency was only 0.16, which ranges between regular earthquakes and tsunami earthquakes. Yet this values changed with time during the rupture process, being initially 0.21 for the southern Sumatra segment and dropping down to 0.053 for the Nicobar segment in the North. The very low value hints to large amounts of energy dissipation associated with water-filled thick sediments.

For another very interesting example of rupture tracking (with animation) of the rather complex Mw8.8 Chile earthquake of 2010 see section 2.6 or IS 1.1. The tracking was made by using records of US Array and permanent California network stations. The rupture was neither unilateral nor bilatetelal but “jumped” several times forth and back in several sub-events covering the whole subsequent aftershock area, which extended over some 600 km.

Nowadays, modern geodetic data may provide very useful independent information on seismic moment tensor, rupture mechanism and magnitude, even in the early warning context, e.g., for real-time predictions of the amplitudes of local tsunami, which strongly depend on the rupture model and source-time function. Sobolev et al. (2006 and 2007) demonstrated how reliable input data for the simulation process, which are for local tsunami mainly the mean and maximum fault slip rather than seismic moment, could be acquired by GPS-Shield

arrays that are strategically deployed on off-shore islands in front of the mainland coasts at risk. But a GPS-Shield array or even a single GPS station can also resolve seismic moment and thus moment magnitude of the rupture with very high accuracy, even if it is located several 100 km away from the trench. As a minimum, the GPS-Shield arrays placed along the trench will allow to estimate  $M_0$  and  $M_w$  for the corresponding sections of a rupture zone (partial magnitude) within just a few minutes of an earthquake.

Additionally, imaging synthetic aperture satellite radar interferometry (INSAR) (nowadays allows to derive reliable information about the areal distribution of surface deformation patterns that have been produced by earthquakes, even if the faults did not rupture through the surface. The interferometric fringe patterns are particularly well developed in vegetation-less arid areas (see Fig. 3.14).

**Fig. 3.14** INSAR Fresnell-zone patterns from the 26 December 2003, Mw 6.5 Bam earthquake, Iran, together with the teleseismic point-source fault-plane solution and the more detailed approximate fault trend (broken white line) with a step-over towards NE as inferred from the Fresnell-zone patterns. The maximum surface uplift and subsidence (in the line of sight to satellite) are 30 cm and 18 cm, respectively, the largest inferred fault slip 270 cm and the estimated total rupture length about 24 km. More than 80% of the seismic moment was released from the southern 13 km long fault segment. This preliminary figure has kindly be made available by R. Wang, GFZ German Research Centre for Geosciences. For more detailed final results and interpretation see Wang et al. (2004).

### 3.1.5 Summary and conclusions

The detailed understanding and quantification of the physical processes and geometry of seismic sources is one of the ultimate goals of seismology, be it in relation to understanding tectonics, improving assessment of seismic hazard or discriminating between natural and anthropogenic events. Earthquakes can be quantified with respect to various geometrical and

physical parameters such as time and location of the (initial) rupture and orientation of the fault plane and slip, fault length, rupture area, amount of slip, magnitude, seismic moment, radiated energy, stress drop, duration and time-history (complexity) of faulting, particle velocity, acceleration of fault motion etc. It is impossible, to represent this complexity with just a single number or a few parameters.

There are different approaches to tackle the problem. One aims at the detailed analysis of a given event, both in the near- and far-field, analyzing waveforms and spectra of various kinds of seismic waves in a broad frequency range up to the static displacement field, complemented by field investigations into macroseismic effects and surface expressions of fault rupture. Such detailed and complex investigations usually require a lot of time and effort. They may be feasible only for selected important events and are usually beyond the scope of routine seismological observatory practice. Nonetheless, we have deliberately dwelled on the issue of source complexity and the multitude of parameters required for describing them adequately. Because many of these parameter have to be derived by detailed analysis of high quality data collected by seismological observatories in a wider sense, permanent or temporary ones, physical or virtual seismic networks (Chapter 8) or seismic arrays (Chapter 9) of local, regional or even global scale or range of operation (see Chapter 8), measuring weak or strong motions.

With dense strong-motion networks deployed in source areas of potentially large earthquakes, as they become now increasingly available in many regions at risk, detailed pictures of the fracture process may already be obtained in near real-time. They are of greatest importance for more reliable shake-map calculations, and thus for a better guidance of relief efforts and as empirical references for both earthquake engineers, land-use planners and others involved in disaster preparedness and mitigation (see Chapter 15).

The second, more simple approach is usually taken at seismological observatories and data centers for the routine analysis of mass data. They describe the seismic source only by a limited number of parameters such as the origin time and (initial rupture) location, magnitude, intensity or acceleration of measured ground shaking, sometimes complemented by fault-plane solutions. These parameters can easily be obtained and have the advantage of rough but quick information being given to the public and concerned authorities. Furthermore, this approach provides standardized data for comprehensive earthquake catalogs which are fundamental for other kinds of research such as earthquake statistics and seismic hazard assessment. But we need to be aware that these simplified, often purely empirical parameters can not give a full description of the true nature and geometry, the time history nor the energy release of a seismic source. In the following we will focus on the most common procedures in routine seismological practice.

## **3.2 Magnitude of seismic events (P. Bormann)**

### **3.2.1 History, scope and limitations of the magnitude concept**

The concept of *magnitude* was introduced by Richter (1935) to provide an objective instrumental measure of the size of earthquakes. The term magnitude was recommended to Richter by H. O. Wood in distinction to the name *intensity* scale, which is based on the assessment and classification of shaking damage and human perceptions of shaking and thus depends on the distance and depth of the seismic source (see Chapter 13). In contrast, the

magnitude  $M$  uses instrumental measurements of the ground motion adjusted for epicentral distance and source depth. Standardized instrument characteristics were originally used to avoid instrumental effects on the magnitude estimates. Thus it was hoped that  $M$  could provide a single number to quantify earthquake size which was also approximately related to the released seismic energy. However, as outlined in 3.1 above, such a simple empirical parameter is not directly related to any physical parameter of the source. Rather, the magnitude scale is currently viewed as providing a quickly determined simple " ... parameter which can be used for first-cut reconnaissance analysis of earthquake data (catalog) for various geophysical and engineering investigations; special precaution should be exercised in using the magnitude beyond the reconnaissance purpose" (Kanamori, 1983).

In the following we will use mainly the magnitude symbols, sometimes with slight modification, as they have historically developed and are still predominantly applied in common practice. However, as will be shown later, such "generic" magnitude symbols are often not explicit enough to specify the type of seismographs, components and phases these magnitudes are based. This requires more "specific" magnitude names where higher precision is required (see IS 3.2). Moreover, in order to assure in future a unique nomenclature, at least for the recently recommended IASPEI standards for widely used magnitudes (see IASPEI 2005 and 2013 as well as IS 3.3), we will use in the following only this new nomenclature when the respective new procedures and so derived data are presented.

The original Richter magnitude,  $M_L$  or  $M_L$ , was based on maximum amplitudes measured on records of the standardized short-period Wood-Anderson (WA) seismometer network in Southern California that are displacement-proportional at periods less than 0.8 s. Such records were suitable for the classification of local shocks in that region. In the following we will name it  $M_l$  (with "l" for "local") in order to avoid on the one hand confusion with more specific names for magnitudes from surface waves where the phase symbol  $L$  stands for unspecified long-period surface waves (e.g., in  $M_{LV}$  or  $M_{LH}$ ), but also, in order to differentiate between local magnitudes scales in general with often unknown scaling, respectively calibration, to the Southern California standard, and those which have been derived and properly scaled according to the new IASPEI recommendations, which are written  $M_L$  or  $M_L$ , respectively.

Gutenberg and Richter (1936) and Gutenberg (1945a, b and c) extended the magnitude concept so as to be applicable to ground motion measurements from medium- and long-period seismographic recordings of both surface waves (written  $M_s$  or  $M_s$ ) and different types of body waves ( $m_B$  or  $m_B$ ) in the teleseismic distance range. For the magnitude to be a better estimate of the seismic energy  $E_s$ , they proposed for  $m_B$  to divide the measured displacement amplitudes by the associated periods to obtain ground velocities and presented in Gutenberg and Richter (1956) the first energy-magnitude relationship  $\log E_s = 2.4 m_B - 1.2$  (when  $E_s$  is given in Joule). Although they tried to mutually scale the different types of magnitudes in order to match at certain magnitude values, it was realized that these scales are only imperfectly consistent with each other. Therefore, Gutenberg and Richter (1956a and b) provided correlation relations between various magnitude scales (see 3.2.9.2).

After the deployment of the World Wide Standardized Seismograph Network (WWSSN) in the 1960s it became customary to determine the body-wave magnitude only on the basis of short-period narrow-band vertical component P-wave recordings only. This short-period body-wave magnitude was termed  $m_b$  (or  $m_b$ ). The introduction of  $m_b$  increased the

inconsistency between the magnitude estimates from body and surface waves. The main reasons for this are:

- different magnitude scales use different periods and wave types which carry different information about the source process and the radiated source spectra;
- the spectral amplitudes radiated from a seismic source increase linearly with its seismic moment for frequencies  $f < f_c$  ( $f_c$  – corner frequency). This increase with moment, however, is reduced for  $f > f_c$  (see Fig. 3.5). This changes the balance between high- and low-frequency content in the radiated source spectra as a function of event size;
- the maximum seismic energy is released around the corner frequency of the displacement spectrum because this relates to the maximum of the ground-velocity spectrum (see Fig. 3.5). Accordingly,  $M$ , when supposed to be a measure of the seismic energy released, strongly depends on the position of the corner frequency in the source spectrum with respect to the pass-band of the seismometer used for the magnitude determination;
- for a given level of long-period displacement amplitude and thus seismic moment  $M_0$ , the position of the corner frequency is mainly controlled by the stress drop in the source (see section 3.1.2.5). Accordingly, high stress drop results in the excitation of more high frequencies (Fig. 3.15) and thus earthquakes with equal  $M_w$  may have rather different energy magnitudes  $M_e$  or short-period magnitudes such as  $m_b$  or  $M_L$ .

**Fig. 3.15** (a) Far-field displacement and (b) velocity source spectra scaled to seismic moment and moment rate, respectively, for a model earthquake with  $M_w = 6.5$  but different stress drop  $\Delta\sigma$  in units of MPa. The spectra were calculated based on the model assumptions explained for Fig. 3.5. The inset in Fig. 3.16(b) shows the variation of the corner frequency  $f_c$  obtained according to the Brune (1970) equation  $f_c = c v_s (\Delta\sigma/M_0)^{1/3}$  in a wider range of  $M_w$  for varying  $\Delta\sigma$  in increments of one order between 0.1 and 100 MPa. (Copy of Fig. 2, p. 415 in Bormann and Di Giacomo 2011: The moment magnitude  $M_w$  and the energy magnitude  $M_e$ : common roots and differences. *J. Seismology*, **15** (2), 411-427; © Springer Publishers).

- seismographs with different transfer functions sample the ground motion in different frequency bands with different bandwidth. Therefore, no one-to-one agreement of the magnitudes determined on the basis of their records can be expected;
- additionally, band-pass recordings distort the recording amplitudes of transient seismic signals, the more so the narrower the bandwidth is. This can not be fully compensated by correcting only the frequency-dependent magnification of different seismographs based on their amplitude-frequency response. Although this is common seismological practice in order to determine so-called "true ground motion" amplitudes for magnitude calculation, it is not fully correct. The reason is that the instrument magnification or amplitude-frequency response curves are valid only for steady-state oscillation conditions, i.e., after the decay of the seismograph's transient response to an input signal (see section 4.5 in Chapter 4). True ground motion amplitudes can be determined only by taking into account the complex transfer function of the seismograph (see Chapter 5) and, in the case of short transient signals, by signal restitution in a very wide frequency band (Seidl, 1980; Seidl and Stammer, 1984; Seidl and Hellweg, 1988). Only recently a calibration function for very broadband P-wave recordings has been published (Nolet et al., 1998), however it has not yet been widely applied, tested and approved (see section 3.2.6.1).

Efforts to unify or homogenize the results obtained by different methods of magnitude determination into a common measure of earthquake size or energy have generally been unsuccessful (e.g., Gutenberg and Richter, 1956a; Christoskov et al., 1985). Others, aware of the above mentioned reasons for systematic differences, have used these differences for better understanding the specifics of various seismic sources, e.g., for discriminating between tectonic earthquakes and underground nuclear explosions on the basis of the ratio  $m_b/M_s$ . Duda and Kaiser (1989) recommend the determination of different spectral magnitudes, based on measurements of the spectral amplitudes from one-octave bandpass-filtered digital broadband velocity records (see section 3.2.6.1).

Another effort to provide a single measure of the earthquake size was made by Kanamori (1977). He developed the seismic moment magnitude  $M_w$ . It is tied to  $M_s$  but does not saturate for big events because it is based on seismic moment  $M_0$ , which is determined via the asymptotic plateau of low-frequency spectral displacement amplitudes for  $f \ll f_c$ . This level increases linearly with  $M_0$ . According to Eq. (3.1),  $M_0$  is proportional to the average static displacement and the area of the fault rupture and is thus a good measure of the total deformation in the source region. On the other hand it is (see the above discussion on corner frequency and high-frequency content) not as good a measure of earthquake size in terms of seismic energy release. This limits the usefulness of  $M_w$  for assessing and specifying the type and severity of seismic hazard and related risks when presented in so-called unified seismic catalogs or in near real-time earthquake alert messages as the only earthquake size parameter. Most earthquake damage is usually related to medium and low-rise structures with eigenfrequencies  $f > 0.5$  Hz (i.e., lower than about 20 stories) and mainly caused by high-frequency strong ground motion. Energy magnitude  $M_e$ , which may differ for some seismic events by one magnitude unit or even more from  $M_w$ , is then a very useful complement, as are the short-period magnitudes  $m_b$  and  $M_l$  that are measured at periods of particular relevance ( $T \approx 0.1$  s to 3 s) for earthquake engineers, engineering seismologists and disaster managers. However, there is no single number magnitude parameter available which could serve alone as a sufficiently reliable estimator of earthquake "size" and related potential

earthquake effects and risks in all their different aspects, tsunami threat included. Because the latter are not directly related to any specific type of the magnitude or the amount of stress drop in the source. Rather, they may be strongly modified by source directivity (see Fig. 3.112), source depth, attenuation conditions along the wave propagation path, wave focusing or defocussing by lateral heterogeneities, the very local site conditions (e.g., in the case of tsunami effects the detailed shallow water bathymetry and coastal configuration) etc. In any event, however, it is advisable to be guided by taking complementary magnitudes into account.

What is needed in practice are at least two parameters to characterize roughly both the source dimensions and the high-frequency energy of a seismic event, namely  $M_0$  and  $f_c$  or  $M_w$  together with  $m_b$  or  $M_l$ , respectively, or a comparison between the moment magnitude  $M_w$  and the energy magnitude  $M_e$  (e.g., Choy and Kirby, 2004; Di Giacomo et al, 2010a; Bormann and Di Giacomo, 2011; and IS 3.5 by G. Choy in this Manual).  $M_e$  can today be determined from direct energy calculations based on the integration of digitally recorded waveforms of broadband velocity (Seidl and Berckhemer, 1982; Berckhemer and Lindenfeld, 1986; Boatwright and Choy, 1986; Kanamori et al., 1993; Choy and Boatwright, 1995) (see section 3.2.7.2 and IS 3.6).

Despite their limitations, common magnitude estimates have proved to be suitable also for getting, via empirical relationships, quick but rough estimates of other seismic source parameters such as the seismic moment  $M_0$ , stress drop, amount of radiated seismic energy  $E_s$ , length  $L$ , radius  $r$  or area  $A$  of the fault rupture, as well as the intensity of ground shaking,  $I_0$ , in the epicentral area and the probable extent of the area of felt shaking (see sections 3.2.6.6 and 3.3.4).

Magnitudes are also crucial for the quantitative classification and statistical treatment of seismic events aimed at assessing seismic activity and hazard, studying variations of seismic energy release in space and time, etc. Accordingly, they are also relevant in earthquake prediction research. All these studies have to be based on well-defined and stable long-term data. Therefore, magnitude values – notwithstanding their inherent systematic biases as discussed above - have to be determined over decades and even centuries by applying rigorously clear and well documented stable procedures and well calibrated instruments. Any changes in instrumentation, gain and filter characteristics have to be precisely documented in station log-books or event catalogs and data corrected accordingly. Otherwise, wrong conclusions may be drawn from research based on incompatible data.

Being aware, on the one hand, of the inherent problems and limitations of the magnitude concept in general and specific magnitude estimates in particular and, on the other hand, of the urgent need to strictly observe reproducible long-term standardized procedures of magnitude determination, we will review below most of the magnitude scales applied in seismological practice. We will then introduce the newly recommended IASPEI measurement standards for some of the widely used magnitude scales. They have been outlined in more detail and commented with respect to their relationship to the classical magnitude scales in IS 3.3. Early comprehensive reviews of the complex magnitude issue have been published by Båth (1966, 1981), the most recent condensed ones were authored by Bormann and Saul (2009a) and Bormann (2011). Various special volumes with selected papers from symposia and workshops on the magnitude problem appeared in *Tectonophysics* (Vol. 93, No.3/4 (1983); Vol. 166, No. 1-3 (1989); Vol. 217, No. 3/4 (1993)).

### 3.2.2. General assumptions and definition of magnitude

Magnitude scales are based on a few simple assumptions, e.g.:

- for a given source-receiver geometry, "larger" events will produce wave arrivals of larger amplitudes at the seismic station. The logarithm of ground motion amplitudes  $A$  is used because of the enormous variability of earthquake generated amplitudes;
- magnitudes should, as preferred by Gutenberg when proposing the  $m_B$  scale, be a measure of radiated seismic energy and thus be proportional to the velocity of ground motion, i.e., to  $A/T$  with  $T$  as the period of the considered wave;
- the decay of ground displacement amplitudes  $A$  with epicentral distance  $\Delta$  and their dependence on source depth  $h$ , i.e., the effects of geometric spreading and attenuation of the considered seismic waves, is known at least empirically in a statistical sense. It can be compensated for by a calibration function  $\sigma(\Delta, h)$ . The latter is the log of the inverse of the reference amplitude  $A_0(\Delta, h)$  of an event of zero magnitude, i.e.,  $\sigma(\Delta, h) = -\log A_0(\Delta, h)$ ;
- the maximum value  $(A/T)_{\max}$  measured on the recorded waveform radiated by a point source of a seismic phase for which  $\sigma(\Delta, h)$  is known should provide the best and most stable estimate of the event magnitude;
- regionally variable preferred source radiation-pattern and *directivity* and/or focusing/defocusing conditions, which may be significant especially in the case of surface waves, may be corrected by (a) regional source correction term(s),  $C_r$ , and the influence of local site effects on amplitudes (which depend on local crustal structure, near-surface rock type, soft-soil cover and/or topography) may be accounted for by a station correction,  $C_s$ , which is assumed not to depend on azimuth.

Accordingly, the general form of all magnitude scales based on measurements of ground displacement amplitudes  $A_d$  and periods  $T$  is:

$$M = \log(A_d/T)_{\max} + \sigma(\Delta, h) + C_r + C_s. \quad (3.13)$$

**Problem 1: Calibration functions used in common practice do not consider a frequency dependence of  $\sigma(\Delta, h)$**

Theoretical calculations by Duda and Yanovskaya (1993) for different attenuation models and by Di Giacomo et al. (2008) for P waves, based on the assumption of  $Q$  values that do not depend on frequency, show that differences in  $A(\Delta, T)$  may become  $> 0.6$  m.u. for  $T < 3$  s, however they are  $< 0.2$  for  $T > 4$  s and thus they are more or less negligible for magnitude determinations in the medium- and long-period range. Yet, magnitude determinations based on the measured ratio  $A/T$ , respectively  $A \times f$ , largely compensate for the frequency-dependent attenuation of  $A$ . Accordingly,  $A/T$  based magnitudes are more stable in a wider range of periods than  $A$  based magnitudes.

In section 3.2.5.2 we will show that the differences in magnitude estimates between short-period  $m_b$ , when  $A$  is measured as the maximum amplitude in the whole P-wave train, and the more long-period magnitude estimates ( $m_B$  and  $M_s$ ) can fully be explained by differences in the frequency at which the amplitudes are measured with respect to the corner frequency of

the radiated source spectrum (see Figs. 3.5 and 3.15). We term this effect the *spectral component of saturation*. Accounting additionally for excessively large attenuation differences at higher frequencies, as proposed by some of the models, would result in even larger differences between teleseismic mb, mostly measured at 0.5 to 2 Hz, mB (mostly measured between  $0.03 \text{ Hz} < f < 0.3 \text{ Hz}$ ) and Ms measured around 20 s period. Therefore, the assumption of frequency-dependent Q according to the absorption model of Liu et al. (1976) seems better to explain both the differences in mb and mB as well as field observations by Der et al. (1982). For the time being, this relaxes the necessity to introduce into the general magnitude formula (3.13) an additional frequency-dependent attenuation term, neither for the two standard body-wave magnitudes nor for the broadband surface-wave magnitude Ms(BB), until better empirical data become available. Yet, this matter requires further studies.

### **Problem 2: $(A/T)_{\max}$ or $(A_{\max}/T)$ ?**

For ease of record analysis it has become widespread practice to measure the easily recognizable largest record amplitude with its period T, to correct it for the period-dependent displacement response and only then to determine the ratio  $A_{\text{dmax}}/T$ . This, however, may not be the real  $(A_d/T)_{\max}$  intended by Gutenberg as a measure of maximum ground motion velocity and thus a close estimator of the radiated seismic energy. Especially, when T is measured in the period range of already steeply dropping amplification of the response curve differences in magnitude estimates may then reach several tenth of magnitude units with respect to the correct procedure (m.u.). This has been identified at the NEIC as a major problem when measuring in records of the WWSSN-SP type (see Fig. 3.19 below) the largest P-wave amplitude at period between about 2 to 3 s. The average deviations as compared to network averages may then reach about +0.5 m.u. (see Fig. 3.16), also when measuring at periods around 0.3 s, which is, however, rarely the case. This lead to the agency decision to calculate mb only from amplitudes measured at periods  $T < 2 \text{ s}$  instead of up to  $< 3 \text{ s}$ , as recommended by the classical mb measurement standard. The reason is that correcting the measured trace amplitudes for the period-dependent instrument response may in the range of the very strong decay of the WWSSN-SP response with 3<sup>rd</sup> order for periods larger than about 1.5 s yield much too large ground amplitudes at already slightly too large measured periods.

**Fig. 3.16** Mean difference between individual station mb and network mb in 0.1 m.u. bins as determined by the NEIC of the US Geological Survey as a function of period at which the maximum amplitude A for mb has been measured (simplified from a Figure by J. W. Dewey et al., 2011 ).

Although not yet fully understood in detail, this problem can obviously be reduced by measuring instead of  $A_{\max}$  on the WWSSN-SP filtered record trace the largest velocity amplitude  $V_{\max} = 2\pi(A/T)_{\max}$  in the time-differentiated WWSSN-SP record trace (see, e.g., Fig. 3.46).. One reason seems to be that - in comparison to WWSSN-SP records – their time-derivatives are more high-frequency with more harmonically looking oscillations and easier to identify related maximum peak-to-trough deflections that really relate to  $(A/T)_{\max}$ . In contrast, WWSSN-SP records tend to be more complex, making it sometimes more difficult to properly read the period which relates to the largest trace amplitude, respectively to the proper  $(A/T)_{\max}$ . This may, as in the case of Fig. 3.17, result in overestimating the  $T$  related to the largest trace amplitude and thus in strong overestimation of the ground motion amplitude  $A$  and thus  $mb$ . Another reason may be that the ground velocity magnification of the WWSSN-SP response decays only with the 2<sup>nd</sup> order towards longer periods. This reduces the adverse effect of measurement errors in  $T$  when converting the measured velocity trace amplitude into ground velocity amplitude.

**Fig 3.17** Comparison of a P waveforms in an unfiltered velocity broadband record (bottom), in the respective WWSSN-SP simulated record (middle), and as a WWSSN-SP velocity trace. Figure amended according to a record plot kindly provided by J. Saul, 2012.

Fig. 3.18a plots the difference  $mb(V_{\max}) - mb(A_{\max}/T)$  for a test data set, both measured automatically. The cluster of strongly negative residuals between -0.4 and -0.65 m.u. relates to standard  $mb$  values measured at periods between 2.1 s and 2.8 s. For shorter periods the deviations between these two versions of  $mb$  measurement have been generally less than 0.2 m.u. with an average absolute deviation of only 0.07 m.u., but 0.11 m.u., when the outliers are included. The mean deviation is about -0.02 with the outliers and slightly positive, + 0.03 m.u., without them. This make  $mb(V_{\max})$  measurements a strong candidate procedure that holds promise to yields with greater ease (no period measurement required) on average  $mb$  values that are compatible with standard  $mb$  yet with greater stability and reduced data scatter. Further studies and documentation on this problem are encouraged.

**Fig. 3.18a** Difference between automatically measured mb values based on measuring the maximum velocity amplitude  $V/2\pi$  on time differentiated WWSSN-SP filtered traces minus mb based on A/T measurement in a wide range of  $\log(A/T)$  of 4 magnitude units. Note the strong outliers despite generally good agreement between these two ways. For explanation see text. (Figure by courtesy J. Saul, GFZ Potsdam).

As one step in this direction, Alberto Michelini from the Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, compared on the request of the Editor for 1155 earthquakes between February 1<sup>st</sup>, 2012, and January 28<sup>th</sup>, 2013, mb(INGV), which is in fact an WWSSN-SP based  $mb(V_{\max})$ , with mb(USGS), which is supposed to be a IASPEI standard mb. The results have been plotted in Fig. 3.18b. One recognizes that the two magnitudes agree on average for the overwhelming majority of data with  $mb(\text{USGS}) < 6.0$  better than 0.1 m.u., yet the difference grows with magnitude up to about 0.3 m.u. The average difference as well as the median of  $mb(\text{USGS})-mb(\text{INGV})$  is 0.06 m.u., the standard deviation  $\pm 0.174$  m.u. and the average absolute deviation 0.145 m.u.

**Fig. 3.18b** **Left:** Histogram of the difference  $mb(\text{USGS})-mb(\text{INGV})$ ; **right:** data plot of  $mb(\text{USGS})$  over  $mb(\text{INGV})$  for 1155 earthquakes with  $4.5 < mb(\text{USGS}) < 7.5$ . The blue line is the 1:1 relationship, the broken black line an eye fit. Figure by courtesy of Alberto Michelini, INGV (2013).

### 3.2.3 General rules and procedures for magnitude measurement

#### 3.2.3.1 General procedures when working with analog data or on digital screen plots

Magnitudes can be determined on the basis of Eq. (3.13) by reading the displacement amplitudes  $A_d$  and their related periods  $T$  for calculating  $(A/T)_{\max}$  for body waves (e.g., P, S, PP) or surface waves (LQ or Lg, LR or Rg) for which calibration functions for either vertical (V) and/or horizontal (H) component records are available. If the period is measured on a seismogram recorded by an instrument whose response is in the considered period range already proportional to velocity, then  $(A_d/T)_{\max} = A_{v\max}/2\pi$ , i.e., the measurement can be directly determined from the maximum trace amplitude of this wave or wave group with only a correction for the velocity gain. In contrast, with displacement proportional records one may not know with certainty where  $(A/T)_{\max}$  is largest in the displacement waveform. Sometimes smaller amplitudes but associated also with shorter periods may yield larger  $(A/T)_{\max}$ . In the following we will always use  $A$  for  $A_d$ , and  $V$  for  $A_v$ , if not otherwise explicitly specified.

In measuring  $A$  and  $T$  from seismograms for magnitude determinations and reporting them to national or international data centers, **the following definitions and respective instructions** given in the Manual of Seismological Observatory Practice (Willmore, 1979) as well as in the recommendations by the IASPEI Commission on Practice from its Canberra meeting in 1979 (slightly modified and amended below) **should have been observed in the past**:

- The trace amplitude  $B$  of a seismic signal on a record is defined as its largest peak (or trough) deflection from the base-line of the record trace.
- For many phases, surface waves in particular, the recorded oscillations are more or less symmetrical about the zero line.  $B$  should then be measured either by direct measurement from the base-line or - preferably - by halving the peak-to-trough deflection (Figs. 3.19 a and c - e). For phases that are strongly asymmetrical (or clipped on one side)  $B$  should be measured as the maximum deflection from the base-line (Fig. 3.19 b).
- The corresponding period  $T$  is measured in seconds between those two neighboring peaks (or troughs) - or from (doubled!) trace crossings of the base-line - where the amplitude has been measured (Fig. 3.19);
- The trace amplitudes  $B$  measured on the record should be converted to ground displacement amplitudes  $A$  in nanometers (nm) or some other stated SI unit, using the  $A$ - $T$  response (magnification) curve  $\text{Mag}(T)$  of the given seismograph (see Fig.3.20); i.e.,  $A = B/\text{Mag}(T)$ . (**Note:** In most computer programs for the analysis of digital seismograms, the measurement of period and amplitude is done automatically after marking the position on the record where  $A$  and  $T$  should be determined).
- Amplitude and period measurements from the vertical component ( $Z = V$ ) are most important. If horizontal components ( $N$  - north-south;  $E$  - east-west) are available, readings from both records should be made at the same time (and noted or reported separately) so that the amplitudes can be combined vectorially, i.e.,  $A_H = \sqrt{(A_N^2 + A_E^2)}$ .
- When several instruments of different frequency response are available (or in the case of the analysis of digital broadband records filtered so as to match different standard responses),  $A_{\max}$  and  $T$  measurements from each should be reported separately and the

type of instrument used should be stated clearly (short-, medium- or long-period, broadband, Kirnos, Wood-Anderson, etc., or related abbreviations given for instrument classes with standardized response characteristics as in Tab. 3.1 and Fig. 3.20 left). For this the classification given in the old Manual of Seismological Observatory Practice (Willmore 1979) may be used.

- Broadband instruments are preferred for all measurements of amplitude and period.
- Note that earthquakes are often complex multiple ruptures. Accordingly, the time,  $t_{\max}$ , at which a given seismic body wave phase has its maximum amplitude may be quite some time after its first onset. Accordingly, in the case of P and S waves, the measurement should normally be taken within the first 25 s and 40-60 s, respectively, but in the case of very large earthquakes this interval may need to be extended to more than a minute. For subsequent earthquake studies it is also essential to report the measurement time  $t_{\max}$  (see Fig. 3.19).
- For teleseismic surface waves (i.e.,  $\Delta > 20^\circ$ ) the procedures are basically the same as for body waves. However,  $(A/T)_{\max}$ , often in the Airy phase of the dispersed surface wave train, occurs much later and should normally be measured in the period range between 16 and 24 s although both shorter and longer periods may be associated with the maximum surface wave amplitudes (see section 2.3 in Chapter 2 and Fig. 3.35 in section 3.2.5.1).
- Note that in displacement proportional records  $(A/T)_{\max}$  may not coincide in time with  $B_{\max}$ . Sometimes, in dispersed surface wave records in particular, smaller amplitudes associated with significantly smaller periods may yield larger  $(A/T)_{\max}$ . In such cases also  $A_{\max}$  should be reported separately. In order to find  $(A/T)_{\max}$  on horizontal component records it might be necessary to calculate  $A/T$  for several amplitudes on both record components and select the largest vectorially combined value. In records proportional to ground velocity, the maximum trace amplitude is always related to  $(A/T)_{\max}$ . Note, however, that as compared to the displacement amplitude  $A_d$  the velocity amplitude is  $A_v = V = A_d 2\pi/T$ .
- If mantle surface waves are observed, especially for large earthquakes (see section 2.3.4 of Chapter 2), amplitudes and periods of the vertical and horizontal components with the periods in the neighborhood of 200 s should also be measured.
- On some types of short-period instruments (in particular analog) with insufficient resolutions it is not possible to measure the period of seismic waves recorded from nearby local events and thus to convert trace deflections properly to ground motion. In such cases magnitude scales should be used which depend on measurements of maximum trace amplitudes only.
- Local earthquakes were often clipped in analog records of high-gain short-period seismographs with insufficient dynamic range. This made amplitude readings impossible. In this case magnitude scales based on record duration (see 3.2.4.5) might be used instead, provided that they have been properly scaled with magnitudes based on amplitude measurements.

**Fig. 3.19** Examples for measurements of trace amplitudes  $B$  and periods  $T$  in seismic records for magnitude determination: a) the case of a short wavelet with symmetric and b) with asymmetric deflections, c) and d) the case of a more complex P-wave group of longer duration (multiple rupture process) and e) the case of a dispersed surface wave train. Note: c) and d) are P-wave sections of the same event but recorded with different seismographs (classes A4 and C) while e) was recorded by a seismograph of class B3 (see Fig. 3.20).

**Tab. 3.1** Example of a bulletin page of station Moxa (MOX), Germany, based on the analysis of analog photographic recordings. The event occurred on January 1967. Note the unambiguous annotation of the type of instruments and component used for the determination of onset times, amplitudes and periods. Multiple body wave onsets of distinctly different amplitudes, which are indicative of a multiple rupture process, have been separated. Types of analog standard seismographs used: A = A4 in Willmore (1979) = short-period with flat displacement response between 0.7 and 10 Hz, B = B3 = in Willmore (1979) = long-period 30-to-80 s seismograph, C = KIRNOS displacement broadband seismograph with flat response between 10 Hz and 20 s as in Fig. 3.20. Components: V = Z = vertical component; H = vectorially combined horizontal components; Lm - maximum of the long-period surface wave train.

**Note** in Tab. 3.1 the distinct differences between the different types of magnitude and the clear underestimation of short-period (type A  $\rightarrow$  mb) magnitudes. This early practice of specifying magnitude annotation has been officially recommended already by the IASPEI Sub-Committee on Magnitudes in 1977 (see Willmore, 1979) but has, regrettably, not become global standard. However, current deliberations in IASPEI stress again the need for more specific magnitude measurements and reports to databases along these lines (see IS 3.2) if the measured data deviate more than 0.1 m.u. from the ones derived for the same type of magnitude calculated by adherence to the newly recommended IASPEI measurement standards. The latter are explained in detail in IS 3.3 of this Manual. Some essential deviations from the above outlined recommendations of the IASPEI Canberra meeting in 1979 are presented in the relevant subsections below with respect to the specific type of magnitude. Determining magnitudes according to more modern and physically based concepts, such as radiated energy or seismic moment, requires special procedures (see IS 3.6 and 3.8-3.10).

Global or regional data analysis centers calculate mean magnitudes on the basis of many A, T and/or M data reported by seismic stations from different distances and azimuths with respect to the source. This will more or less average out the influence of regional, source and local station conditions. Therefore, A, A/T or M data reported by individual stations to such centers should not yet be corrected for  $C_r$  and  $C_s$ . These corrections can be determined best by network centers themselves when comparing the uncorrected data from many stations (e.g., Hutton and Boore, 1987). They may then use such corrections for reducing the scatter of individual readings and thus improve the average estimate.

When determining new calibration functions for the local magnitude  $M_L$ , station corrections have to be applied before the final data fit in order to reduce the influence of systematic biases on the data scatter. According to the procedure proposed by Richter (1958) these station corrections for  $M_L$  are sometimes determined independently for readings in the N-S and E-W components (e.g., Hutton and Boore, 1987). When calculating network magnitudes some centers prefer the median value of individual station reports of  $M_L$  as the best network estimate. As compared to the arithmetic mean it minimizes the influence of widely diverging individual station estimates due to outliers or wrong readings (Hutton and Jones, 1993).

**Fig. 3.20** Relative magnification curves for ground displacement for various types of standardized classical seismographs. **Left:** as a function of period according to Willmore (1979) and **right:** as a function of frequency as in Chapter 11.

**WA** = Wood-Anderson seismograph, which was instrumental in the definition of the local magnitude scale;

**C** = KIRNOS – short-to-medium-/long-period Russian broadband seismograph operated at all first-rate stations of the former Soviet Union and its allied countries as well as in China, which was instrumental in developing the Moscow-Prague  $M_s$  magnitude calibration function applicable in a wide range of surface-wave periods;

**A4** = Kirnos SKM short-period seismograph of relatively broad bandwidth;

**A2** = WWSSN-SP = short-period and

**B1** = WWSSN-LP = longperiod seismograph of the World Wide Standardized Seismograph Network (WWSSN), set up by the United States Geological Survey (USGS) in the 1960s and 1970s, which were instrumental for measuring short-period P-wave magnitude  $m_b$  and the long-period  $M_s$  around 20 s periods;

**B3** = US High Gain Long-Period seismograph with maximum magnification around 40 s;

**SRO-LP** – long-period high-gain seismograph of the U.S. Seismological Research Observatories (SRO) for measuring 20 s surface-wave amplitudes and magnitudes with best signal-to-noise ratio by strongly filtering out 6 s ocean microseisms.

### 3.2.3.2 Aim and specified general procedures for IASPEI standard magnitudes and possible modifications in automated procedures (P. Bormann, J. Saul, and S. Wendt)

IASPEI has established in 2002 within its Commission on Seismic Observation and Interpretation (CoSOI) a Working Group on Magnitude Measurements (in the following for short named the WG Magnitude) in an effort to assure

- homogeneity and long-term global compatibility of magnitude data and their usefulness for seismic hazard assessment and research and therefore
- best possible agreement with magnitudes of the same type that have been measured for decades from analog seismograms according to original definitions, as well as
- unambiguity in the nomenclature of magnitude data of similar type but measured with different procedures

aiming at

- minimizing bulletin magnitude biases that result from procedure-dependent single-station or network magnitude biases,
- increasing the number of seismological stations and networks with well-defined procedures and
- promoting the best possible use of the advantages of digital data and processing.

As of now, this WG has agreed on standard measurement procedures for five widely used magnitudes: ML, mb, mb(Lg), Ms(20), mB(BB) and Ms(BB). For details see the latest version IASPEI (2013) of the recommendations of the Working Group of Magnitude Measurements as well as a more elaborated version with comments in IS 3.3.

Of general importance is that these standard magnitudes have to be measured on either simulated records of classical analog seismographs or on unfiltered digital broadband records:

- ML on Wood-Anderson (WA) records;
- mb and mb-Lg on WWSSN-SP records;
- Ms(20) on WWSSN-SP records.
- mB(BB) and Ms(BB) on unfiltered broadband records with a velocity-proportional response over at least the period range in which mB(BB) ( $T = 0.2 \text{ s}$  to  $30 \text{ s}$ ) and Ms(BB) ( $T = 3 \text{ s}$  to  $60 \text{ s}$ ) should be measured.

For the approximate shape of the response curves of WA, WWSSN-SP and –LP see Fig. 3.20 above, for the more precise normalized response curves and their respective poles and zeros see Figure 1 and Table 1 in IS 3.3.

Note that for the international data exchange and archiving the nomenclature of the standard magnitudes should be written in the (for magnitude data maximum of) 5-character IASPEI Standard Format (ISF; see Chapter 10), which would be ML, mb, mb\_Lg, Ms\_20, mB\_BB and Ms\_BB.

In contrast to the classical magnitude formulas, which are based on displacement amplitudes  $A$  measured in units of  $\mu\text{m}$ , amplitude readings for standard magnitudes should all be reported

in units of nm (for A) or in nm/s (for velocity amplitudes V measured on unfiltered BB records). Therefore, the commonly known classical calibration relationships have been modified for the standard magnitudes to be consistent with these new units.

The measured amplitudes have to be reported following their so-called **amplitude phase names**, which are specified for the respective magnitudes as: IAML, IAmb, IAmb\_Lg, IAMs\_20, IVmB\_BB and IVMs\_BB. Tab. 10.5 in Chapter 10 gives an example how these amplitude data, also for other non-standard magnitudes, appear now in IMS1.0/ISF parameter format in the event and station parameter plots produced by the USGS/NEIC HYDRA automatic location and analysis system.

The current recommendations for amplitude and period measurements for the new **IASPEI magnitude standards** orient themselves essentially on what has been described above with Fig. 3.18 and is still dominating practice when analyzing analog records or digital screen plots. According to IS 3.3 these recommendations read as follows:

*“The amplitudes used in the magnitude formulas ... are in most circumstances to be measured as one-half the maximum peak-to-adjacent-trough (sometimes called “peak-to-peak”) deflection of the seismogram trace. None of the magnitude formulas presented in this article are intended to be used with the full peak-to-trough deflection as the amplitude. The periods normally are to be measured as twice the time-intervals separating the peak and adjacent-trough from which the amplitudes are measured. The amplitude-phase arrival-times are normally to be measured as the time of the zero-crossing between the peak and adjacent-trough from which the amplitudes are measured.”*

Although the calculation of the broadband magnitudes mB\_BB and Ms\_BB, now based on direct measurement of  $V_{\max}$ , do no longer require that the periods are measured, the WG Magnitude strongly encourages their complementary measurement and reporting, since the period at which  $V_{\max}$  appears in broadband records is closely related to the corner frequency of the radiated source spectrum and thus is of interest also for other users of these data.

Furthermore, **we have to accept that their might be agency-specific circumstances that may lead to the modification of standard procedures, e.g., of measuring amplitudes and periods or using modified types of responses. But then certain rules should be obeyed (see sections 3.5 and 5 in IS 3.3) and a careful documentation of station/agency magnitude procedures be assured (see questionnaire in Annex 2 to IS 3.4).** The latter should be posted on the station/agency website and also be deposited and kept updated at the ISC for the information of data users.

While the visual recognition and picking of the dominating amplitudes and related periods is relatively easy interactively for an experienced analyst on a computer screen or record plot, even in the case of rather complex superimposed waveforms as in Fig. 3.17, or 3.21b below, it is much more difficult for a definite algorithm to handle properly all possible ramifications of such a measurement problem. Agencies which run automatic procedures of data analysis, may therefore prefer to measure as amplitude just the maximum positive or negative deflection between two zero crossings of the record trace and to estimate the zero position from the long-term average prior to the respective wave onset. The related period is then taken, e.g., as twice the timedifference between the respective zero crossings. This may be easier to handle automatically. However, in order to check whether such a modified automatic measurement procedure, but also an automatic procedure which is supposed to mimic best the

recommended measurement standards, yield indeed magnitude estimates within  $\pm 0.1$  m.u. of standard magnitudes measured manually or interactively by an expert analyst, this has to be tested and documented by comparative measurements. They should use an identical representative test data set in a wide range of magnitudes or  $\log(A/T)$  and  $\log(V/2\pi)$  values, respectively. Only when the results agree with an average absolute deviation less than about 0.1 m.u., the automatic data, or those derived with any other modified measurement procedure, can be accepted as being in agreement with the standards and thus can be reported to international agencies or in agency bulletins with the IASPEI amplitude-phase-name nomenclature.

We demonstrate this by way of example for period and amplitude measurements for mb, mB\_BB, Ms\_20 and Ms\_BB. The interactive analysis has been carried out by S. Wendt, CLL observatory of the University Leipzig, Germany, and the automatic analysis by J. Saul, GFZ German Research Centre for Geosciences at Potsdam. The latter tested two versions of rather simple but very fast and stable test algorithms, intended to be used with masses of globally retrieved waveform data in the tsunami early warning context. This sets limits with respect to algorithm flexibility and sophistication.

Fig. 3.21 gives an example of period measurements on a WWSSN-SP waveform for mb and on a velocity broadband waveform for mB\_BB. Fig. 3.22 summarises the median and average ratios  $T_{\text{manual}}/T_{\text{automatic}}$  and their standard deviations when measuring mb, mB\_BB, Ms\_20 and Ms\_BB.

**Fig. 3.21** P waveforms on **a)** a simulated WWSSN-SP record and **b)** on an unfiltered velocity broadband record to explain some of the possible complications of automatic amplitude and period measurements as compared to manual readings. The width of the **blue column** corresponds to  $T/2$  when measuring as amplitude half of the vertical distance between the maximum peak and the maximum adjacent trough (for short peak-to-trough = ptp; marked as **bold black record trace**) and as period twice the time difference between ptp, as recommended by the standard. In contrast, the width of the **red column** corresponds to reading  $T/2$  between the two adjacent zero crossings related to the largest (here negative) swing, when measuring as amplitude the largest zero-to-peak (or trough) deflection, in the following termed ztp for short. For comments on Fig. 3.21 see text.

When looking at the two waveforms in Fig. 3.21 one realizes that for an analyst there is no difficulty at all to properly determine  $A$  and  $T$  according to the standard recommendation based on ptp readings, even on the broadband trace with a distinct superposition of various

periods. The dominant one, related to the absolute  $V_{\max}$ , is without any doubt. Yet, in the BB velocity record of Fig. 3.21b T/2 manual peak-to-trough (= ptp in blue) is about 3 times T/2 ptp automatic (in red), because the simple algorithm got trapped in a secondary adjacent peak just after the zero crossing from below. A more sophisticated algorithm, which would recognize the difference between a secondary adjacent and the **maximum** adjacent peak would surely have got about the same period as an analyst.

Luckily, differences in T at which  $V_{\max}$  is measured do not matter when calculating mB\_BB. Only asymmetry between the corresponding largest positive and negative half cycle amplitudes makes a difference when comparing ptp/2 with zero-to-peak (ztp) amplitude measurements. In our case, however, the difference between **manual** ptp/2 and automatic ztp is minimal (**0.02 m.u.**). In contrast, the difference between the tested **automatic** ptp/2 and automatic ztp results is nearly **0.3 m.u.**, which would be the theoretical maximum for single-sided swings. Yet, on the smoother P waveform in Fig. 3.21a the current ptp/2-algorithm had not difficulties to correctly read A and T. In contrast, the automatic ztp-algorithm measured on this waveform a much too large period between the related two zero crossings. In view of the steep WWSSN-SP response drop for periods larger than 1.5 s, a much too large A was calculated, resulting in a **0.6 m.u. larger mb value than mb(IASPEI)** (see section 3.2.2, **Problem 2**, Figs. 3.16 and 3.18 and related discussion).

Fig. 3.22 summarizes the results of our comparative period measurements for all four teleseismic standard magnitudes. The average ratios  $T_{\text{automatic}}/T_{\text{manual}}$  are close to 1 for mb, Ms\_20 and Ms\_BB with very small standard deviation SD. Worst are the mean and SD for mB\_BB. On the other hand the median ratio is best for the two broadband magnitudes mB\_BB and Ms\_BB. This indicates that outliers in period estimates in conjunction with mB\_BB measurements, which can not be prevented with the here tested automatic ptp/2 algorithm, seem to bias both the mean and SD significantly. However, the generally good agreement between manual and automatic period determinations according to the standard recommendation is very encouraging.

| Period ratios: |                                            |                                            |
|----------------|--------------------------------------------|--------------------------------------------|
| mb:            | $T_{\text{automatic}} / T_{\text{manual}}$ | mean = $1.025 \pm 0.004$<br>median = 1.007 |
| mB_BB:         |                                            | mean = $0.850 \pm 0.023$<br>median = 1.000 |
| Ms_20:         |                                            | mean = $0.996 \pm 0.001$<br>median = 0.997 |
| Ms_BB:         |                                            | mean = $1.027 \pm 0.003$<br>median = 1.000 |

**Fig. 3.22** Period ratios  $T_{\text{automatic}}/T_{\text{manual}}$  (median, mean and standard deviation) for the teleseismic standard magnitudes mb, mB\_BB, Ms\_20 and Ms\_BB when measured according to the 2 times peak-to-trough rule.

Next we compare in Fig. 3.23 various combinations of automatic and manual mB\_BB measurements.

**Fig. 3.23** Differences of mB\_BB values (ordinates of the upper three figures) between automatic and manual ptp/2 procedures (upper left), fully automatic ztp and ptp/2 procedure (upper middle), and automatic ztp compared with manual ptp/2 procedure (upper right). The analyzed records cover a wide range of earthquakes with magnitudes  $5.3 \leq mB\_BB \leq 8.3$ . In the middle row the percentage of differences  $> \pm 0.1$  m.u. is given. The long red arrows point to the respective magnitude difference values in the uppermost three diagrams that result from applying the respective procedure combination to the waveform depicted in the bottom diagram.

From Fig. 3.23 the following conclusions can be drawn:

- Different algorithms of automatic mB\_BB determination may yield results which significantly differ from each other or from competent manual mB\_BB measurements.
- Best agreement between automatic and manual mB\_BB calculations is achieved with the current ptp/2 test algorithm. The single outlier of nearly  $-0.3$  m.u. is due to the algorithm getting stuck in a secondary peak near to the zero line. Only in two more cases the difference between automatic and interactive readings is slightly larger than  $0.1$  m.u., probably again due to taking some secondary maxima/minima as largest adjacent peak or trough, yet further away from the zero line. In summary, it is most likely, that the tested automatic ptp/2 procedure yields overwhelmingly standard compatible mB\_BB data. The median difference in our test with 39 events is  $+0.01$  m.u. and the average absolute difference  $0.03$  m.u., reducing to  $0.02$  m.u. without the single large outlier.
- If the algorithm could be upgraded so as to avoid getting trapped in secondary extrema of different polarity adjacent to the primary amplitude maxima or minima then the automatic mB\_BB measurements would be perfectly compatible with manual standard measurements.

- The agreement between automatic ztp and manual ptp/2 measurements is somewhat inferior. In about 13% of the studied cases residuals are  $> 0.1$  m.u., but always  $< 0.2$  m.u. with the average absolute deviation 0.04 m.u.
- The disagreement is largest between fully automatic ztp and ptp/2 derived mB\_BB values. In about 25% of the cases the difference is  $> 0.1$  m.u. and may reach about 0.3 m.u. with a median of 0.07 and an average absolute deviation of almost 0.05 m.u. This is not compatible with IASPEI standard requirements.

Fig. 3.24 shows a similar comparison of automatic and manual mb procedures.

**Fig. 3.24** Difference in m.u. between automatically and manually determined mb values in the magnitude range  $5.0 \leq mb \leq 7.6$ : **a)** automatic – manual ptp/2 measurement; **b)** automatic ztp – manual ptp/2 measurement; **c)** WWSSN-SP waveform with the ztp negative half swing marked in red from which A and T were measured that produced the data point with the largest difference of almost 0.6 m.u. in diagram b).

From Fig. 3.24 the following conclusions can be drawn:

- mb yields more data than mB\_BB for smaller events but with much larger scatter.
- For about 84% of the analyzed waveforms, **the ptp/2 test algorithm yielded mb values that agreed within 0.1 m.u. with those determined by manual expert analysis.** Both arithmetic mean and median difference are within 0.01 m.u. from zero. Therefore, the ptp/2 algorithms hold promise to produce overwhelmingly mb values that are compatible with IASPEI standard mb. Despite sometimes large outliers the median difference is zero and the average absolute deviation between automatic and manual ptp/2 measurements for mb only 0.05 m.u.
- Yet, outliers up to 0.6 m.u. are not acceptable for standard magnitude data that aim at drastically reducing procedure-dependent errors. Therefore, for assuring IASPEI compatible amplitude, period and mb values in the agency bulletins and data reports to international data centers either the algorithm has to be improved or expert control of the final data is indispensable.
- The negative outliers of mb are again due to the ptp/2 algorithm getting occasionally trapped in secondary adjacent maxima or minima (see above discussion for mB\_BB).
- Significant positive outliers may be due to overestimating the period T (see the 2-3s problem discussed above), usually at rather small  $\log(A/T)$  values due to superposition

with more long-period noise amplitudes which is not recognized and properly accounted for by the automatic algorithm.

- **The ztp-algorithm**, which still worked reasonably well for mB\_BB, **does not yield standard compatible results for mb**. Average and median difference are already about 0.1 m.u., the standard deviation is  $\pm 0.16$  m.u. and the average absolute difference to ptp/2-based manual analysis 0.11 m.u. Accordingly, for about  $\frac{3}{4}$  of the analyzed waveforms the difference to manual ptp/2 measurement was larger than 0.1 m.u., with positive and negative outliers up to about 0.4-0.6 m.u.

Figs. 3.25 and 3.26 show such comparisons also for broadband Ms\_BB and narrowband Ms\_20.

**Fig. 3.25** Difference in m.u. between automatically and manually determined velocity broadband Ms\_BB values in the magnitude range  $4.6 \leq \text{Ms\_BB} \leq 9.0$ : **a)** automatic – manual ptp/2 measurement; **b)** automatic ztp – manual ptp/2 measurement; **c)** automatic ztp – ptp/2 measurement.

**Fig. 3.26** Difference in m.u. between automatically and manually determined velocity broadband Ms\_20 values in the magnitude range  $4.8 \leq \text{Ms\_20} \leq 9.0$ : **a)** automatic – manual ptp/2 measurement; **b)** automatic ztp – manual ptp/2 measurement; **c)** automatic ztp – ptp/2 measurement.

Comments and conclusions related to Fig. 3.25 and 3.26 are the following:

- For both  $M_s$  magnitudes automatic and manual A/T and  $V_{\max}$  readings based on ptp/2 yield in most cases comparable values, yet the average agreement is clearly better and the data scatter less for  $M_s_{\text{BB}}$  (mean difference -0.01 m.u., SD =  $\pm 0.07$  m.u. and average absolute deviation of 0.02 m.u. only, as compared to  $M_s_{20}$  with -0.02,  $\pm 0.25$  and 0.07 m.u. respectively).
- For only about 8% of the data automatic ptp/2  $M_s_{\text{BB}}$  differed more than  $\pm 0.1$  m.u. from the manually measured ones, for  $M_s_{20}$  this applied to about 10% of the data.
- **The differences between automatic ztp and manual ptp/2 are even less.** For  $M_s_{\text{BB}}$  the agreement is even perfect, with the exception of a single but relatively large (+0.35 m.u.) outlier, which is in fact the same for  $M_s_{20}$ .
- The reason for this single large outlier turned out to be an event association error by the automatic algorithm. It searches for the maximum surface-wave amplitude within a given time window after the P-wave onset. The time window depends on distance and a fixed group-velocity window assumed for the surface waves. In the current algorithm, the group velocity window covers the range between 2.5 and 4.5 km/s. With this wide window, applied to two Chile earthquake aftershocks, following each other within 17 min, the algorithm measured as the largest surface-wave amplitude for both  $M_s_{\text{BB}}$  and  $M_s_{20}$  that of the about 0.3 m.u. larger later aftershock, the analyst, however, the surface-wave maxima measured by the analyst, however, related correctly to the earlier aftershock. This wrong association accounts also for the identically large positive outlier when comparing the automatic and manual ptp/2 results for  $M_s_{\text{BB}}$  and  $M_s_{20}$  in Figs. 3.25 and 3.26. The lesson is, that proper association of surface-wave maxima related to closely following events are generally more difficult for an algorithm which has to operate blind with a fixed set of parameters than for an off-line working intelligent analyst. Therefore, before final data cataloguing and reporting to international data centers automatically calculated magnitude data should go through an expert review.
- While there are no negative residuals at all for  $M_s_{\text{BB}}$  when comparing automatic ztp with manual ptp/2, there are 3 negative ones when comparing automatic and manual ptp/2, and even 6 in the case of  $M_s_{20}$ . One of the negative outliers for both  $M_s_{\text{BB}}$  (-0.27 m.u.) and  $M_s_{20}$  (-0.25 m.u.) was again due to the wrong association of the automatically measured surface-wave maximum to another event that occurred within the same hour but at rather different distance and thus arrived at the recording station again close to the surface-wave maximum of another event. And one more of the 3 negative  $M_s_{\text{BB}}$  residuals (-0.22 m.u.) was caused by missing the later arriving absolute  $V_{\max}$  for  $M_s_{\text{BB}}$  within the preset group velocity and measurement time window, which, however, worked fine for this event for the earlier arriving  $M_s_{20}$  amplitude maximum..
- **Only for  $M_s_{\text{BB}}$  the tested automatic ztp and ptp/2 algorithms yielded practically identical results within  $< 0.1$  m.u.**

Tab. 3.2 summarizes the essential statistical results of the above procedure comparison.

**Tab. 3.2** Statistic parameters of comparing automatic magnitude calculations based on ztp and ptp/2 amplitude measurements with manual ptp/2 measurements according to IASPEI standard procedures. **Mauto** = type of magnitude, measured automatically, **N** = number of measured differences between automatic and manual magnitude determinations; **Median** = median difference, **Mean** = arithmetic mean of differences, **SD** = standard deviation from the mean, **Avad** = average absolute difference, **% > 0.1** = approximate percentage of differences larger than 0.1 m.u., **Max outliers**. **Note:** all calculated median, mean, SD and avad values have been rounded to the nearest second decimal. Since the distribution of differences is not Gaussian the median and avad values are more relevant to assess the agreement with the strict standard procedure. Mauto procedures in best agreement with the manual standard procedure have been written in bold letters.

Summarizing our procedure comparison test we conclude:

- The current automatic GFZ algorithm for determining teleseismic magnitudes of the types mb, mB\_BB, Ms\_20 and Ms\_BB have been developed in the first instance for application in the tsunami early warning systems, i.e., for very fast and stable applications to great amounts of globally accessible waveform data. Therefore, ztp has so far been given preference for ptp/2 in operational applications.
- Yet, our investigations showed, that the ztp algorithm is – with the exception for Ms\_BB – inferior (often not much but worst for mb) to the ptp/2 algorithm, which is closer to the preferred IASPEI standard procedure.
- However, with the exception for mb, both algorithms yield (when taking into account the median, respectively the mean differences, standard deviations, and average absolute differences as well as the real distribution of residuals) magnitude estimates which differ in less than 20%, for the ptp/2 version even in less than 10% of the cases, magnitude values that are within 0.1 m.u of manual expert estimates.
- The differences could be further reduced, for body-wave magnitude estimates in particular, by using a more sophisticated ptp/2 algorithm that avoids getting trapped in a secondary maximum or minimum by searching for the **largest adjacent** amplitude with opposite polarity to the primary maximum deflection from the zero line..

- Automatic algorithms for surface waves have to search for the maximum amplitude within a flexible time window, depending on distance and a preset group velocity window. If the latter is chosen too small it may fail or yield to small values when applied to Ms\_BB measurements in a wide range of periods and distances. And when the group velocity window is chosen too wide, the algorithm may measure instead of the searched for surface-wave maximum of an earlier and/or weaker event the later following larger maximum of an overlapping event, closely spaced in time of arrival. Our data have been affected by such cases.
- Event association errors, and likely also mistakes in proper peak-to-trough association in the case of complex waveforms, can hardly be excluded for sure in automatic procedures of magnitude determination that are based on preset algorithm parameters. Therefore, automatically determined magnitude data should be critically checked by expert analysts before they enter final bulletins or are reported to international data centers for final use and archiving.
- Generally, in any such comparison of different magnitude measurement procedures, differences beyond the acceptable level of measurement errors of about 0.10-0.15 m.u. should not be considered as random noise. Usually they have a non-random cause. Therefore, one should strive to identify their reasons. This requires, however, that one goes back for the specific data points to their respective waveforms and compare which amplitudes and periods have been measured by what method and at which time. If the reasons for significant residuals have become clear this may also offers the chance to reduce the data scatter by modifying the algorithm. This we have tried to demonstrate by way of example.
- Another lesson from our demonstration is that one should avoid in such comparisons that the selected reference waveform data contain overlapping wave groups belonging to different events in order to avoid large outliers due to wrong associations.

In the following we will outline the origin, general features, formulae and specific differences of various magnitude scales that are currently in use or recommended by the IASPEI WG on Magnitudes. We will highlight which of these scales are at present already accepted as world-wide standards and will also spell out related problems which still require further consideration, clarifying discussion, recommendations or decisions by CoSOI. Data tables and diagrams on calibration functions used in actual magnitude determinations are given in Datasheet 3.1.

### 3.2.4 Magnitude scales for local and regional events

The large variability of velocity and attenuation structure of the crust does in fact not permit the development of a unique, internationally standardized calibration function for local events. However, the original definition of magnitude by Richter (1935) did lead to the development of a local magnitude scale  $M_L$  (original nomenclature  $ML$ ) for California.  $M_L$  scales for other areas are usually scaled to Richter's or Hutton and Boore's (1987) definition and also the procedure of measurement is more or less standardized. With slight modification, the Hutton and Boore formula has now been accepted by IASPEI as the reference formula for standard  $ML$  to which other regional  $M_L$  scales should be scaled in order to yield compatible results within about 0.1 m.u. for equal measurement values at different distances.

### 3.2.4.1 The original Richter magnitude scale $M_L$

In his 1935 landmark paper Richter stated:

*„...it is frequently desirable **to have a scale** for rating these shocks in terms of their original energy, independently of the effects which may be produced at any particular point of observation.“*

For his measurements he used Wood-Anderson (WA) horizontal component torsion seismometers which had become available and widely deployed as a standard instrument in the 1930s in Southern California. According to the manufacturer the **WA seismometers** had the following parameters: natural period  $T_S = 0.8$  s, damping factor  $D_S = 0.8$ , **static magnification**  $V_{\max} = 2800$ . The resulting response is sketched in Fig. 3.27 left..

**Fig. 3.27 Left:** Wood-Anderson response according to manufacturer's instrument data; **Right:** Plot of original data measured by Richter; copy of Figure 22-2 in Richter (1958).

Following a recommendation by Wadati, Richter plotted the logarithm of maximum **trace amplitudes**,  $A_{\max}$ , measured on WA records as a function of epicentral distance  $\Delta$ . He found that  $\log A_{\max}$  decreased with distance along more or less parallel curves for earthquakes of different size (Fig. 3.20 (right)). This led him to propose the following definition for the magnitude as a quantitative measure of earthquake size (Richter 1935, p. 7):

*"The magnitude of any shock is taken as the logarithm of the maximum trace amplitude, expressed in microns, with which the standard short-period torsion seismometer ... would register that shock at an epicentral distance of 100 km".*

This local magnitude was later given the symbol  $M_L$  (Gutenberg and Richter, 1956b). In order to calculate  $M_L$  also for other epicentral distances,  $\Delta$ , between 30 and 600 km, Richter (1935) provided attenuation corrections. They were later complemented by attenuation corrections for  $\Delta < 30$  km assuming a focal depth  $h$  of 18 km (Gutenberg and Richter, 1942; Hutton and Boore, 1987). Accordingly, one gets

$$M_L = \log A_{\max} - \log A_0 \quad (3.14)$$

with  $A_{\max}$  in mm of measured zero-to-peak trace amplitude in a Wood-Anderson seismogram. The respective calibration values  $-\log A_0$  were published in tabulated form by Richter (1958) (see Table 1 in DS 3.1). Fig. 3.28 summarizes the classical procedure of ML determination.

According to this original definition of the local magnitude scale  $ML = ML$  by Richter (1935), only the *maximum trace amplitude*  $B$  in mm as recorded in standard records of a Wood-Anderson seismometer is measured, i.e.:

$$ML = \log B(WA) - \log A_0(\Delta).$$

⇒ no period  $T$  is measured, and **NO CONVERSION** to “ground motion” amplitude  $A$  by correcting for the frequency-dependent seismograph magnification is made.

$$ML = \log B(WA) - \log A_0(\Delta)$$

$$ML = 1.36 + 3.46 = 4.82$$

Calibration function  $\sigma_1(\Delta) = -\log A_0$  for local magnitudes  $ML$  according to Richter (1958).  $A_0$  are the trace amplitudes in mm recorded by a Wood-Anderson Standard Torsion Seismometer from an earthquake of  $ML = 0$ .  $\Delta$  - epicentral distance in km.

| $\Delta$ (km) | $\sigma_1(\Delta)$ | $\Delta$ (km) | $\sigma_1(\Delta)$ | $\Delta$ (km) | $\sigma_1(\Delta)$ | $\Delta$ (km) | $\sigma_1(\Delta)$ |
|---------------|--------------------|---------------|--------------------|---------------|--------------------|---------------|--------------------|
| 0             | 1.4                | 90            | 3.0                | 260           | 3.8                | 440           | 4.6                |
| 10            | 1.5                | 100           | 3.0                | 280           | 3.9                | 460           | 4.6                |
| 20            | 1.7                | 120           | 3.1                | 300           | 4.0                | 480           | 4.7                |
| 30            | 2.1                | 140           | 3.2                | 320           | 4.1                | 500           | 4.7                |
| 40            | 2.4                | 160           | 3.3                | 340           | 4.2                | 520           | 4.8                |
| 50            | 2.6                | 180           | 3.4                | 360           | 4.3                | 540           | 4.8                |

**Fig. 3.28** Summary of the classical procedure of measuring  $ML$ . Note that the letter  $B$  was given here to record trace amplitudes, highlighting that they were not been converted to ground motion displacement amplitudes  $A$ .

**Note 1:** According to Uhrhammer and Collins (1990) the magnification of 2800 of WA seismometers had been calculated on the basis of wrong assumptions on the suspension geometry. **More correct values** for the static magnification and the damping of the seismometer are  $2080 \pm 60$  and  $D_s = 0.7$ , respectively (see also Uhrhammer et al., 1996). Accordingly, **magnitude estimates based on synthesized WA records** assuming the original WA parameters systematically underestimate the size of the event. This underestimation depends on the frequency at which the amplitude is measured. It is on average at typical periods about 0.1 m.u., has its minimum around the corner frequency of 0.128 Hz ( $T = 0.8$  s; 0.065 m.u.) and is largest (up to 0.13 m.u.) at significantly lower and higher frequencies (Fig. 3.29). However, as long as records of original WA seismographs are used this bias plays no role.

**Fig. 3.29** **a)** Response curves of Wood-Anderson seismometers calculated for different static magnification and damping. Upper left: Original manufacturer's response; upper right: **red** response curve according to Uhrhammer and Collins (1990) when correcting only for the difference in static magnification; lower right: red curve: as upper right but additionally accounting for the difference in seismometer attenuation. **b)** differences in ML (m.u.): red line – correcting only for difference in static magnification; blue curve – accounting additionally for the difference in seismometer damping; black curve – difference between red and blue. (Figure by courtesy of D. Bindi, 2011).

**Note 2:** In contrast to the general magnitude formula (3.13), Eq. (3.14) considers only the maximum displacement-proportional record amplitudes but not their periods. Reason: WA instruments are short-period and their traditional analog recorders had a limited paper speed. Proper reading of the period was difficult. It was assumed, therefore, that the maximum

amplitude phase (in case of local events generally Sg, Lg or Rg) had always about the same dominant period within the plateau range of the response. Also,  $-\log A_0$  does not consider a depth dependence of  $\sigma(\Delta, h)$ . Seismicity in southern California is generally shallow (mostly less than 15 km). Eq. (3.14) also does not give regional or station correction terms. They were already taken into account when determining  $-\log A_0$  for southern California.

**Note 3:** In the following we use as the general NMSOP nomenclature for local magnitude data  $M_l$  (with  $l$  = local), unless the respective data have been measured and calibrated for sure according to the new IASPEI  $M_l$  standard or they relate directly to the original Richter scale.

**Note 4:** The smallest events recorded in local microearthquake studies have negative values of  $M_l$  while the largest  $M_l$  is about 7, i.e., the  $M_l$  scale also suffers “saturation” (see Fig. 3.47). Despite these limitations,  $M_l$  estimates of earthquake size are relevant for earthquake engineers and risk assessment since they are closely related to earthquake damage. The main reason is that many structures have natural periods close to that of the WA seismometer (0.8s) or are within the range of its pass-band (about 0.1 - 1 s).

### Problems and conclusions:

- 1) In 3.2.3 it was said that in the case of horizontal component recordings, as a general IASPEI rule,  $A_{Hmax}$  should be the maximum vector sum amplitude measured at  $t_{max}$  in both the N and E component. Deviating from this, Richter (1958) says: “... *In using ...both horizontal components it is correct to determine magnitude independently from each and to take the mean of the two determinations. This method is preferable to combining the components vectorially, for the maximum motion need not represent the same wave on the two seismograms, and it even may occur at different times.*” In most investigations aimed at deriving local  $M_l$  scales  $A_{Hmax} = (A_N + A_E)/2$  has been used instead to calculate  $M_l$  although this is not fully identical with  $M_l = (M_{lN} + M_{lE})/2$  and might give differences in magnitude of up to about 0.1 m.u.
- 2) The Richter  $M_l$  from arithmetically averaged horizontal component amplitude readings will be smaller by at least 0.15 magnitude units as compared to  $M_l$  from  $A_{Hmax}$  vector sum. In the case of significantly different amplitudes  $A_{Nmax}$  and  $A_{Emax}$  this difference might reach even several tenths of magnitude units. However, the method of combining vectorially the N and E component amplitudes, as generally practiced in other procedures for magnitude determination from horizontal component recordings, is hardly used for  $M_l$  because of reasons of continuity in earthquake catalogs, even though it would be easy nowadays with digital data.
- 3) According to Hutton and Boore (1987) the *distance corrections developed by Richter for local earthquakes ( $\Delta < 30$  km) are incorrect*. Bakun and Joyner (1984) had come to the same conclusion for weak events recorded in Central California at distances of less than 30 km. This leads to magnitude estimates from nearby stations that are smaller than those from more distant stations. Therefore, Hutton and Boore (1987) proposed that local magnitude scales be redefined such that  $M_l = 3$  corresponds to 10 mm of motion on a WA record at 17 km hypocentral distance. This is consistent with the original definition of the scale for Southern California and will also allow a better comparison of earthquakes in regions with very different wave attenuation within the first 100 km.

- 4) According to Hutton and Jones (1993) redetermination of local magnitudes recorded by the Southern California Seismographic Network (SCSN) from 1932 to 1990 has shown that the magnitudes have not been consistently determined over that period of time. The amplitudes recorded on WA instruments were systematically overestimated prior to 1944 compared to present reading procedures, leading to a significant overestimation of ML. Moreover, the change to computerized estimation in 1975 led to slightly lower event magnitudes for the time after. These obviously not well documented, thought over and agreed upon changes contributed to an apparently higher rate of seismicity in the 1930s and 1940s than later in the catalog, which had been misinterpreted as a decrease in seismicity rate after the 1952 Mw7.5 Kern County earthquake. Rereading WA amplitudes for moderate earthquakes ( $M_l \geq 4.5$ ) for the whole time span resulted in magnitudes which proved to be Poissonian distributed with no significant change in seismicity above the 90% level.
- 5) Similar experiences with other local and global catalogues led Habermann (1995) to state: “... the heterogeneity of these catalogues makes characterizing the long-term behaviour of seismic regions extremely difficult and interpreting time-dependent changes in those regions hazardous at best.... Several proposed precursory seismicity behaviors (activation and quiescence) can be caused by simple errors in the catalogues used to identify them. ....Such mistakes have the potential to undermine the relationship between the seismological community and the public we serve.”

The points stated above highlight the urgency for standardization of measurement procedures and of careful documentation of introduced changes and their reasons. Only this can assure the unambiguous reproduction of so important event parameters such as magnitude and enable - if required – their correction for assuring long-term stability and representativeness of earthquake catalogs.

For a review of the development and use of the Richter scale see Boore (1989).

### 3.2.4.2 The new IASPEI standard ML

In order to avoid several of the above mentioned problems and inconsistencies in ML determination and to reduce related data scatter and/or level discrepancies the IASPEI/CoSOI Working Group on Magnitude Measurements recommends the following for **IASPEI standard ML** (for more details and discussions see IS 3.3):

*“For crustal earthquakes in regions with attenuative properties similar to those of Southern California, the proposed standard equation is*

$$ML = \log_{10}(A) + 1.11 \log_{10}R + 0.00189 \cdot R - 2.09, \quad (3.15)$$

*where  $A$  = maximum **trace** amplitude in **nm** that is measured on output from a **horizontal-component** instrument that is filtered so that the response of the seismograph/filter system replicates that of a **Wood-Anderson standard seismograph** but with a static magnification of 1 (see Table 1 and Figure 1 in IS 3.3) and  $R$  = **hypocentral distance in km**, typically less than 1000 km.”*

Note that equation (3.15) is an expansion of that proposed by Hutton and Boore (1987). The constant term -2.09 is based on the experimentally determined attenuation and static magnification of the Wood-Anderson instrument by Uhrhammer and Collins (1990), rather than on the respective parameters specified earlier by the manufacturer (see discussion and Fig. 3.29 in 3.2.4.1). Further, the WG states:

*“For seismographic stations containing two horizontal components, amplitudes are measured independently from each horizontal component, and each amplitude is treated as a single datum. There is no effort to measure the two observations at the same time, and there is no attempt to compute a vector average.*

*For crustal earthquakes in regions with attenuative properties that are **different** than those of coastal California, and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:*

$$ML = \log_{10}(A) + C(R) + D, \quad (3.16)$$

*where A and R are as defined in equation (here 3.15), except that A may be measured from a **vertical-component** instrument, and where C(R) and D have been **calibrated** to adjust for the different regional attenuation and to adjust for any systematic differences between amplitudes measured on horizontal seismographs and those measured on vertical seismographs.”*

Procedures to synthesize the responses of other seismographs from digital broadband recordings are meanwhile common knowledge (e.g., Plešinger et al., 1995 and 1996). Therefore, WA seismographs are no longer required for carrying out ML determinations. Savage and Anderson (1995) and Uhrhammer, et al. (1996) demonstrated the ability to determine an unbiased measure of local magnitude from synthetic WA seismograms. Thus, a seamless catalog of ML could be maintained at Berkeley, California. In a first approximation (although not identical) this may also be achieved by converting record amplitudes from another seismograph with a displacement frequency response  $\text{Mag}(T_i)$  into respective WA trace amplitudes by multiplying them with the ratio  $\text{Mag}_{\text{WA}}(T_i)/\text{Mag}(T_i)$  for the given period of  $A_{\text{max}}$  (see EX 3.1). Sufficient time resolution of today’s high-frequency digital records is likewise no longer a problem.

**Note:** See sections 4.1 and 5.1.1 in IS 3.3 for differences between Richter’s (1935) and the now standard formula (3.15) as well as for admissible modifications of the WA response for improving the SNR and still enabling unbiased ML estimates of very weak earthquakes.

### 3.2.4.3 Other ML scales based on amplitude measurements

As highlighted by the IASPEI recommendation for an ML standard, Richter’s and also Hutton and Boore’s attenuation corrections can only be assumed valid for Southern California. More recently, a new calibration function has been agreed upon for all California and vicinity (Uhrhammer et al., 2011). But shape and level of these California calibration functions may be different from those applicable in other regions of the world with different velocity and attenuation structure, crustal age and composition, heat-flow conditions and depth distribution of earthquakes. Accordingly, when determining ML calibration functions for other regions, the amplitude attenuation law has to be determined first and then this curve has to be scaled to the

original definition of ML at 100 km epicentral distance (or at closer distance as recommended by Hutton and Boore, 1987; see Problem 3 in 3.2.4.1). Some examples for other regional ML calibration functions have been plotted in Fig. 3.30. Formulas for these and many more regional calibration functions are given in Table 2 of DS 3.1 together with comments on their scaling, components to be used and the distance range of applicability. Those for continental shield areas revealed significantly lower body-wave attenuation when compared with Southern California (e.g., the calibration curve of Alsaker et al., 1991, in Fig. 3.30. Therefore, despite proper scaling to California ML at or near to  $\Delta = 100$  km, their calibration and thus derived ML values for equal amplitude input data may already be several tenths of magnitude units smaller at several hundred km distance.

**Fig. 3.30** Calibration functions for ML determination in different regions. Some of them extend well beyond the 600 km distance plotted here, e.g., that of Alsaker et al. (1991) up to 1500 km. At the latter distance  $-\log A_0$  differs by 1.7 magnitude units from the extrapolated calibration curve for southern California. Even at much shorter distance, such as 320 km for a demonstration event recorded at station MOX, the difference is already to 0.5 m.u.

The problem of vector summing of amplitudes in horizontal component records or of arithmetic averaging of independent ML determinations in N and E components can be avoided by measuring the maximum amplitude on vertical component recordings instead, provided that the respective  $-\log A_0$  curves are properly scaled to the original definition of Richter at  $\Delta = 100$  km or at shorter distances, as proposed by Hutton and Boore (1987) and done, e.g., for Tanzania (Langston et al., 1998), for better compensation of near range differences in attenuation properties and in the depth distribution of earthquakes. Several vertical component formulas have been proposed also for other regions (see. Table 2 of DS 3.1). At large distances, sometimes well beyond the distance of 600 km for which  $-\log A_0$  was defined by Richter (1958), these formulas mostly pertain to Lg waves. Alsaker et al. (1991) and Greenhalgh and Singh (1986) showed that  $A_{Zmax} \approx 1$  to 1.2 times  $A_{Hmax} = 0.5 (A_{Nmax} + A_{Emax})$  and thus yields practically the same magnitudes.

**Note 1:** Station corrections in some of these studies varied between -0.6 to +0.3 magnitude units (Bakun and Joyner, 1984; Greenhalgh and Singh, 1986; Hutton and Jones, 1993) and correlated broadly with regional geology. This points to the urgent need to determine both calibration functions and station corrections for ML on a regional basis.

**Note 2:** Since sources in other regions may be significantly deeper than in southern California, either  $\sigma(\Delta, h)$  should be determined or at least the epicentral distance  $\Delta$  be replaced in the magnitude formulas by the "slant" or hypocentral distance  $R = \sqrt{(\Delta^2 + h^2)}$ . The latter is now common practice. E.g., the  $M_L$  scale for Kamchatka is based on the 1968 modified version of Fedotov's (1963) K-scale (see IS 3.7, Figure 5) and is defined as  $M_L = 0.5 K_S - 0.75$ . It uses the maximum ratio  $A/T$  for S-waves scaled against the S-P traveltime (which is approximately proportional to  $R$ ). The calibration curve  $\sigma(S-P)$  for the K-scale is the averaged one over three depth bins in the depth range 0-200 km.  $M_L$  defined in this way is well correlated en masse with event  $m_b$  (A. Gusev, personal communication 2013).

**Note 3:** There have been efforts to develop frequency-dependent regional calibration functions, e.g., for Central Europe (Wahlström and Strauch, 1984; see Fig. 3.30). But this breaks with the required continuity of procedures and complicates the calibration relationship for  $M_L$ .

**Note 4:** Increasing availability of strong-motion records and their advantage of not being clipped even by very strong nearby events have led to the development of (partially) frequency-dependent  $M_L^{SM}$  scales for strong-motion data (Lee et al., 1990; Hatzidimitriou et al., 1993). The technique to calculate synthetic Wood-Anderson seismograms from strong-motion accelerograms was first introduced by Kanamori and Jennings (1978). In any event, the best way to make  $M_L^{SM}$  values best compatible with standard  $M_L$ , the broadband strong-motion records have to be pre-processed by applying double integration so as to produce the respective broadband displacement equivalent (with the uncertainty of the unknown integration constants). Then a WA simulation filter should be applied (see section 3.1 in IS 3.3 and for a general application example Margaritis and Papazachos, 1999) before measuring the amplitudes. And, most importantly, a local/regional displacement calibration function carefully scaled to that in (3.15) has to be available.

#### 3.2.4.4 $m_b$ \_Lg

Short-period Lg waves with periods  $T < 3$  s (see Chapter 2, 2.3.3 and definition in IS 2.1) die out even along short oceanic travel path but they may travel far with comparably low attenuation (e.g., in comparison with Sg) through the continental crust. This applies especially to travel paths of Lg in cratonic platform areas, such as those in North America and Eurasia. Accordingly, while Sg may no longer be recognizable Lg may become the prominent phase at distances above a few hundred km (see Fig. 2.17 in Chapter 2) and well recordable up to about 30° epicentral distance.

The Lg phase is a complicated seismic signal. It is comprised of many surface-wave higher modes having group velocities around 3.5 km/s. Lg energy is strongly scattered by crustal heterogeneities (Knopoff et al., 1973; Bouchon, 1982; Kennett, 1985 ; Xie and Lay, 1994 and 1995). This complexity of Lg results in a very effective averaging of both the source radiation and crustal wave propagation effects. Therefore, statistical measures of Lg, such as rms amplitudes over a specified group velocity window, yield for given propagation paths very stable and accurate relative estimates of source strength, e.g., Lg magnitude values, which are useful in nuclear test discrimination and yield estimation (Xie and Lay, 1995). However, regional calibration for different travel paths is a prerequisite.

Lg magnitudes are calibrated either with respect to (or in a similar way as) Ml or to teleseismic mb. In the latter case they are usually termed mbLg or Mn (Ebel, 1982). Thus, when scaled to match with teleseismic mb at larger distances, a respective mb\_Lg scale, covering the range between 4° and 30° (as originally proposed by Nuttli (1973) can bridge the gap between more local Ml scales and teleseismic (D > 20°) mb.

Moreover, mb\_Lg has proven to yield rather stable magnitude estimates, even for single stations (Mayeda, 1993), with low scatter and thus good input data for estimating the yield of underground nuclear explosions (UNE) (e.g., Nuttli, 1986, Hansen et al., 1990). Further, since teleseismic P-wave records from earthquakes with magnitudes mb around 4 or less usually suffer of very low signal-to-noise ratio, mb\_Lg permits to extend the discrimination capability between UNE and natural earthquakes on the basis of the Ms-mb criterion down to Ms = 2.5 (Patton and Schlittenhardt, 2005; Richards, 2002). This has made mb\_Lg to a preference magnitude in the test-ban control community (e.g., Zhao et al., 2008). Yet, mb\_Lg has also become a favorite regional magnitude in general seismological practice of North America, southern Asia and in several northern European states such as Denmark, Finland and Norway (see **EMSC-CSEM Newsletter of Nov. 15, 1999** via <http://www.emsc-csem.org/Documents/?d=newsl>). One should note, however, that some of the so-called Lg scales are often not proper mb\_Lg - as shortly sketched below - but rather extensions of Ml, scaled to California Ml and not to teleseismic mb, yet measuring Lg amplitudes up to much greater distances than common for chiefly Sg-based Ml.

Nuttli (1973) was first to propose a conventional type of formulas for mb(Lg) for the eastern United States that have been routinely used at the NEIC:

$$\text{mb(Lg)} = 3.75 + 0.90 \cdot \log_{10} \Delta + \log (A/T) \text{ for } 0.5^\circ < \Delta < 4^\circ, \quad (3.17)$$

and

$$\text{mb(Lg)} = 3.30 + 1.66 \cdot \log_{10} \Delta + \log (A/T) \text{ for } 4^\circ < \Delta < 30^\circ, \quad (3.18)$$

where  $\Delta$  = distance in degrees, A = ground motion amplitude of Lg waves in microns, and T = period in seconds in the range 0.5 to 1.5 s.. A is the magnification-corrected, sustained (3<sup>rd</sup> largest peak) amplitude in the Lg train, measured on vertical-component, short-period (SP) WWSSN seismograms and corrected for period-dependent magnification.

The two log-linear formulas, which match at  $\Delta = 4^\circ$ , were required in order to approximate the empirical (A/T) observations in the Central U.S., which the exponential decay laws of Ewing et al. (1957), sufficiently well. And the constants had to be chosen such that mb(Lg) agrees for moderate size earthquakes in the U.S. with teleseismic mb(P).

Båth et al. (1976) developed a similar Lg scale for Sweden which is widely used in Scandinavia. Street (1976) recommended a unified mbLg magnitude scale between central and northeastern North America. Herrmann and Nuttli (1982) showed (later also Kim, 1998) that mbLg values are commonly similar to Ml when based on amplitude readings with periods around 1 s. They also proposed to define regional attenuation relations so that mbLg/Mn from different regions predict the same near source ground motions, i.e., that the mbLg scale becomes “transportable”. This new magnitude equation employs two terms to correct for amplitude decay (2<sup>nd</sup> term = geometrical decay and 3<sup>rd</sup> term = attenuation) and it requires that the attenuation  $\gamma$  of 1-Hz Lg waves is known beforehand. The formula reads:

$$mb(Lg) = 3.81 + 0.83 \cdot \log_{10} \Delta + \gamma \cdot (\Delta - 0.09^\circ) \cdot \log e + \log A, \quad (3.19)$$

where  $e = 2.718$ . Note that in this formula just amplitude  $A$  and not  $(A/T)$  is measured, again on WWSSN-SP records but in an even narrower range of period (0.8 s to 1.2 s). The constant in this formula was also determined by scaling  $mb(Lg)$  to teleseismic  $mb(P)$ . Specifically, for earthquakes in central United States, an  $Lg$  amplitude  $A$  of 115  $\mu m$  at distance  $0.09^\circ$  had to yield an  $mb = 5.0$  to be consistent with teleseismic magnitudes. This differs from the conventional  $mb(Lg)$  formula which yields at this distance an  $A/T$  of 155  $\mu m/s$  for  $mb = 5$ .

Herrmann and Kijko (1983) developed a frequency-dependent scale  $mLg(f)$  in order to broaden the frequency domain within which  $mbLg$  is applicable. Ebel (1994) proposed  $mLg(f)$ , calibrated to  $mb$  and computed with appropriate  $Lg$  spatial attenuation functions, to become the standard for regional seismic networks in northeastern North America. Ambraseys (1985) published calibration  $Q_g$  (for  $Sg$  and  $Lg$ ) and  $Q_R$  (for crustal Rayleigh waves), respectively that are applicable for northwestern European earthquakes in the distance range  $0.5^\circ < D < 11^\circ$ .

The final form of an amplitude-based  $mb(Lg)$  formula has been proposed by Nuttli (1986) and is written in two parts: First a corrected “hypothetical”  $Lg$  amplitude at distance 10 km =  $0.09^\circ$  is calculated on the basis of the general Ewing et al. (1957) decay law that fits best the empirical regional attenuation curves and then, in a second step,  $mb(Lg)$  using this hypothetical amplitude, normalized to 110  $\mu m$ , and the calibration constant. These formulas read:

$$A(10) = A(\Delta) \cdot (\Delta/10)^{1/3} \cdot [\sin(\Delta/111.1) / \sin(10/111.1)]^{1/2} \cdot \exp[\gamma \cdot (\Delta - 10)] \quad (3.20)$$

$$\text{and} \quad mb(Lg) = 5.0 + \log [A(10)/110], \quad (3.21)$$

where  $A(\Delta)$  is sustained ground motion amplitude in  $\mu m$  and  $\Delta$  is distance in km. The minor deviations from the earlier Herrmann and Nuttli (1982) formulas are, besides the scaling to 110  $\mu m$  instead of 115  $\mu m$ , that the acceptable period range has been somewhat relaxed (0.7 s to 1.3 s) and that only amplitudes in the group velocity window of 3.6 to 3.2 km/s should be measured.

Based on the formulas developed by Nuttli (1986) and Herrmann and Nuttli (1982) the CoSOI Working Group on Magnitude Measurement recommended now (see IASPEI, 2013 and/or IS 3.3) the following **IASPEI standard formula for  $mb(Lg) = mb\_Lg$** :

$$mb\_Lg = \log_{10}(A) + 0.833 \log_{10}[r] + 0.4343 \gamma (r - 10) - 0.87 \quad (3.22)$$

where  $A$  = “sustained ground-motion amplitude” in **nm**, defined as the third largest amplitude in the time window corresponding to group velocities of 3.6 to 3.2 km/s, in the period ( $T$ ) range 0.7 s to 1.3 s;  $r$  = **epicentral distance in km**;  $\gamma$  = coefficient of attenuation in  $km^{-1}$ .  $\gamma$  is related to the quality factor  $Q$  through the equation  $\gamma = \pi/(Q \cdot U \cdot T)$ , where  $U$  is group velocity and  $T$  is the wave period of the  $L_g$  wave.

*A and T are measured on output from a **vertical-component** instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a WWSSN **short-period** seismograph. Arrival times with respect to the origin of the seismic disturbance are used, along with epicentral distance, to compute group velocity  $U$ .”*

**Note:** “ $\gamma$  is a strong function of crustal structure and should be determined specifically for the region in which the mb\_Lg is to be used.”

Benz et al. (1997) describe in detail the procedure applied and the values derived in a comprehensive regional Lg attenuation survey for the continental United States.

The approximate equations (3.17) and (3.18) of Nuttli (1973) yield mb\_Lg that are about 0.1 m.u. smaller than those of the proposed standard procedure when  $\gamma = 0.00063 \text{ km}^{-1}$  in equation (3.22). Yet, preference is given to the proposed standard formula because of its transportability to regions with attenuation different than that of eastern North America (Nuttli, 1986; Patton, 2001).

**Recent researches** on mb\_Lg and regional variation of Lg attenuation **commonly use root-mean-square (RMS) amplitude measurements** rather than measurements made at a single peak (e.g., Patton and Schlittenhardt, 2005; Phillips and Stead, 2008). The use of RMS amplitudes offers the promise of more precise mb\_Lg measurements (according to Mayeda, 1993, with roughly 25% smaller residuals as compared to single amplitude mb\_Lg), but will require the development of a new formula, which should then be calibrated with respect to equation (3.22). See in this context also the last paragraph in the next section on Md and Mc. Developing the mb(Lg) scale for central Europe, Patton and Schlittenhardt (2005) had to calibrate all GRSN stations for site terms and for differences in Lg attenuation, because lateral variations in Lg Q turned out to be significant across the study area. Therefore, a regional Q model consisting of constant-Q partitions north, south and in the central Alps had to be developed.

#### 3.2.4.5 Duration and coda magnitudes (Md or Mc)

The pioneer in proposing earthquake magnitude determination via total signal duration has been the Hungarian seismologist Bisztricsany (1958). He scaled the time difference from the first P onset until then end of the surface-wave train in teleseismic records to magnitude. His method becomes now again of interest in estimating roughly the seismic moment of strong historical earthquakes from their duration in records of well defined historical instruments. Widely applied, however, have been duration magnitudes Md only since the late 1960s for local earthquakes. The simplest one is the coda magnitude (Mc), developed as a complement or alternative to single-amplitude based Ml. Signal codas are formed by scattered waves, i.e., waves which did not travel the minimum paths between seismic source and receiver, being reflected and diffracted by lateral inhomogeneities of the propagation medium. The stronger the primary signal, the larger the signal-to-noise ratio and thus the coda duration d. Different procedures are applied for determining signal or coda duration such as:

- duration from the P-wave onset to the end of the coda, i.e., where the signal disappears in the seismic noise of equal frequency, as in Fig. 3.31);
- duration from the P-wave onset to that time when the coda amplitudes have decayed to a certain threshold level, given in terms of average or RMS signal-to-noise ratio or of absolute signal amplitudes or signal level. This is objective, reproducible and best suited for automatic coda length determination, not, however, for manual ones.
- total elapsed time = coda threshold time minus origin time of the event.

Thus  $d$  becomes a good estimator of signal strength or event magnitude, which is in the local range, in agreement with single scatter theories, even independent on recording distance when the total elapse time is taken (Aki and Chouet, 1975). Yet, it is also possible to estimate the magnitude of large earthquakes even at teleseismic distances by using the P-wave coda (Houston and Kanamori, 1986). Another distinct advantage of  $M_d$  is that coda amplitudes depend much less than maximum phase amplitudes on source radiation pattern and directivity (Masuda, 1992).

One of the main reasons, however, for developing  $M_d$  scales was that analog paper or film recordings had a very limited dynamic range of only about 40 dB and analog tape recordings of about 60 dB. Even the dynamic range of early digital recorders with 12 or 16 bit A-D converters and thus 66 dB or 90 dB, respectively, was not yet enough to assure unclipped seismic records and  $A_{\max}$ -based magnitude determinations in the case of strong earthquakes recorded at local and regional distances.

In contrast,  $M_d$  (or  $M_c$ ) scales are based on either the total signal duration or the duration of the most pronounced coda of the Sg and/or Lg phase of an event. Coda length can easily be estimated even on clipped records of low dynamic range. However, with 24 bit A-D converters and  $\approx 140$  dB usable dynamic range now being standard, clipping is usually no longer a pressing problem. It is rare that an event is not considered for analysis because of clipped record traces.

Note that scattering efficiency on small-scale heterogeneities depends on wavelength. Codas of seismic phases (also termed *signal-generated noise*) are well developed in short-period but not in long-period records and more pronounced in bandlimited than in broadband records (see Figs. 4.12-14 in Chapter 4). Moreover, SNR conditions at station and network sites influence the Coda-SNR and thus the measured coda length above noise level. Therefore,  $M_d$  scales should be developed for networks with given instrumentation (gain and bandpass range), noise conditions and practice a uniquely specified way of measuring signal duration and choosing the screen scaling appropriately. Fig. 3.31 illustrates to some extent, how variations in these parameters and related uncertainty in picking the coda end may influence the calculated  $M_d$  values.

Moreover, one should also know that short coda length ( $< 10$  s) are not a stable measure of earthquake size since they do not yet contain the backscattered energy from more distant heterogeneities (Aki and Chouet, 1975). Thus, one can not expect a generally valid relationship for  $M_d$  calculation for both small (in the near range only recorded) and large events (recorded also at larger distances) (e.g., Bakun and Lindh, 1977).

According to Aki and Chouet (1975) coda waves from local earthquakes are commonly interpreted as back-scattered waves from numerous heterogeneities uniformly distributed in the crust and that only one scatterer has been met by not-minimum path rays before reaching the station. Therefore, for a given local earthquake **at epicentral distances shorter than 100 km** the total duration of a seismogram is almost independent of distance and azimuth and of structural details of the direct wave path from source to station. Also the shape of coda envelopes, which decay exponentially with time (see Fig. 3.22), remains practically unchanged. The dominating factor controlling the amplitude level of the coda envelope and signal duration is then the earthquake size. This allows development of duration magnitude scales without a distance term if coda duration is measured from the origin, i.e.:

$$M_d = a_0 + a_1 \log d. \quad (3.23)$$

Thus, quick magnitude estimates from local events are feasible even without knowing the exact distance of the stations to the source.

**Fig. 3.31** Unfiltered (1<sup>st</sup> and 3<sup>rd</sup> trace) and filtered record traces of a local event with  $M_L = 2.8$  at station FOO in Norway in 117 km epicentral distance, with the 3<sup>rd</sup> and 4<sup>th</sup> traces being amplified for better noise resolution. Note the significant differences in  $M_c = M_d$  estimates using formula (3.27) below, depending on where one picks the end of the coda. High-pass filtering and record amplification may aid a more realistic picking. (Copy of Fig. 6.7 in Havskov and Ottemöller (2010); © Springer publishers).

At larger distances and with multi-scattering involved, also distance comes into play. A theoretical description of the coda envelopes as an exponentially decaying function with time and linear dependence on distance was presented by Herrmann (1975). He proposed a duration magnitude formula of the more general form:

$$M_d = a_0 + a_1 \log d + a_2 \Delta. \quad (3.24)$$

Most coda wave magnitude relationships are of this general type and use measured coda lengths larger than 30 s.

Havskov and Ottemöller (2010) show by way of example that the large variations in the formula parameters determined for different regions and thus the great variability of calculated  $M_d$  values for equal values of  $d$  are much larger than common for  $A_{\max}$ -based  $M_L$  scales. They also argue that most of these differences are due to different ways of measuring coda length and to differences in SNR conditions but not so much due to different tectonics and attenuation conditions.

A very early formula for the determination of local magnitudes based on signal duration was developed for earthquakes in Kii Peninsula in **Central Japan** by Tsumura (1967) and scaled to the magnitudes  $M_{JMA}$  reported by the Japanese Meteorological Agency:

$$M_d = 2.85 \log (F - P) + 0.0014 \Delta - 2.53 \quad \text{for } 3 < M_{JMA} < 5 \quad (3.25)$$

with  $P$  as the onset time of the  $P$  wave and  $F$  as the end of the event record (i.e., where the signal has dropped down to be just above the noise level),  $F - P$  in s and  $\Delta$  in km (also in all later following relationships)

Another duration magnitude equation of the same structure has been defined by Lee et al. (1972) for the **Northern California** Seismic Network (NCSN). The event duration,  $d$  (in s), is measured from the onset of the  $P$  wave to the point on the seismogram where the coda amplitude has diminished to 1 cm on the Develocorder film viewer screen with its 20 times magnification. With  $\Delta$  in km these authors give:

$$M_d = 2.00 \log d + 0.0035 \Delta - 0.87 \quad \text{for } 0.5 < M_l < 5. \quad (3.26)$$

The location program HYPO71 (Lee and Lahr, 1975) employs Eq. (3.25) to compute duration magnitudes, called FMAG. But it was found that Eq. (3.25) yields seriously underestimated magnitudes of events  $M_l > 3.5$ . Havskov and Ottemöller (2010) also calculated the greatest differences of this formula as compared to other formulas developed for other regions. Therefore, several new duration magnitude formulae have been developed for the **NCSN**, all scaled to  $M_l$ . One of the latest versions by Eaton (1992) uses short-period vertical-component records, a normalization of instrument sensitivity, different distant correction terms for  $\Delta < 40$  km,  $40 \text{ km} \leq \Delta \leq 350 \text{ km}$  and  $\Delta > 350 \text{ km}$ , as well as a depth correction for  $h > 10 \text{ km}$ .

Formulas according to (3.24) were also derived for **Norway** by Havskov and Sørensen (2006):

$$M_d = 3.16 \log d + 0.0003 \Delta - 4.28 \quad \text{for } 0.5 \leq M_l \leq 5, \quad (3.27a)$$

for **Mexico** by Havskov and Macias (1983):

$$M_d = 2.40 \log d + 0.00046 \Delta - 1.59 \quad \text{for } 3 \leq M_l \leq 6, \quad (3.27b)$$

for **East Africa** Dindi et al. (1995):

$$M_d = 1.9 \log d + 0.0004 \Delta - 1.2 \quad \text{for } 3 \leq M_l \leq 5, \quad (3.27c)$$

and for Northwestern Italy by Bindi et al. (2005) with significantly different coefficients for each stations of a network of 12 stations, ranging for the constant term between -1.7 and -2.7, for the distance term between  $(2.8 \text{ and } 4.9) \times 10^{-3}$  and for the duration term between 1.77 and 2.61.

In contrast, other formulas, mostly for smaller earthquakes recorded at shorter distances, were developed according to the general relationship (3.23), i.e., without a distance term for scaling smaller earthquakes recorded at closer distances, such as

by Bakun and Lindh (1977) for **California**:

$$M_d = 0.71 \log d + 0.28 \quad \text{for } 0.5 \leq M_l \leq 1.5, \quad (3.28a)$$

by Viret (1980) for the **eastern USA**:

$$M_d = 2.74 \log d - 3.38, \quad (3.28b)$$

and by Castello et al. (2007) for **Italy**, with mostly large station corrections  $Sc_j$  for stations in Southern Italy:

$$M_d = 2.49 \log d - 2.31 + Sc_j \quad \text{for } 1.5 \leq M_l \leq 4.5, \quad (3.29)$$

Other  $M_d$  formulas used in **Albania, France, Italy, Portugal** and former **Yugoslavia** can be found in the **EMSC-CSEM Newsletter of Nov. 15, 1999** via <http://www.emsc-csem.org/Documents/?d=newsl>), for **Greece** in Kiratzi and Papazachos (1985), for **Sweden** in Wahlström (1979), for the Vogtland swarm earthquakes in **Germany** in Klinge (1989), for the **Caucasus** area in Rautian et al. (1979) and for **Japan** in Masuda (1992).

According to Eaton (1992), average station residuals between amplitude- and duration-based local magnitude estimates are practically independent of distance from the epicenter to at least 800 km. Moreover, when properly scaled mutually, the difference between these two independent estimates is, when averaged over 0.5 m.u. intervals, less than 0.05 in the magnitude range  $M = 0.5$  to  $M = 5.5$ .

**Note:** Crustal structure, scattering and attenuation conditions vary from region to region and even from station to station (local site effects). The latter seem to dominate both amplitude-based and duration-based magnitude residuals. Older well-consolidated rocks produce negative residuals (due to smaller amplitudes and shorter durations) and younger unconsolidated rocks produce positive residuals (Eaton, 1992). No general formulas can therefore be given. They must be determined locally for any given station or regionally for every network and be properly scaled to the best available amplitude-based  $M_l$  scale. In addition, the resulting specific equation will depend on the chosen definition for  $d$ , the local noise conditions, the sensor response and gain operated at the considered seismic station(s) of a network.

Moreover, with  $mb\_Lg$  scales using increasingly coda envelopes instead of third peak or RMS amplitudes, they become a version of coda magnitudes scales  $Mc$ . Mayeda (1993), using 1-Hz  $Lg$ -coda envelopes, thus made very stable single-station estimates of magnitudes from Nevada test site underground nuclear explosions. Rautian et al. proposed already in 1981 the use of coda amplitude, not of duration, in the definition of coda-based magnitudes, since coda spectral amplitudes are closely related to the earthquake source spectrum (Rautian and Khalturin, 1978). Coda-amplitude based  $Lg$ -magnitude estimates have generally a five times smaller scatter. Rautian et al. (1981) designed two particular scales based on the records of short-period (SP) and medium-period (MP) instruments. A scale of this kind is still used routinely by the Kamchatka seismic network (Lemzikov and Gusev, 1989 and 1991; see also IS 3.7). The main advantage of such magnitude scales is their unique intrinsic accuracy; even a single-station estimate has a root-mean-square (RMS) error of only 0.1 or even less.

### 3.2.4.6 The Russian K-class system for classifying earthquakes

For quantifying the size of local and regional earthquakes in terms of released seismic energy the energy class (K-class) system has been developed since the late 1950s in the former Soviet Union (FSU). For small and moderate earthquakes in the catalog “*Earthquakes in the USSR*” only K values are given, supplemented by magnitude values based on body and surface-wave readings only for larger, world-wide recorded earthquakes (see section 3.2.5 on common teleseismic magnitude scales and Table 4 in DS 3.1).

Nature, origin, and methodology of the K-class system are poorly known to western seismologists studying Soviet and Russian seismological data, yet they are of great interest and importance to those conducting detailed research on the seismicity of the former USSR (FSU) with the aim to make it also quantitatively compatible with other seismicity data and maps on a regional and global scale (Rautian et al., 2007; Mackey et al., 2010). We have, therefore, added to NMSOP-2 an elaborate new information sheet **IS 3.7**. It outlines in detail the conditions to be met and the assumptions made in developing the K-scale, looks into the conversion relationships between different regional K-scales and ISC mb and Ms as well as Mw and Me magnitude.

K-class was defined as  $K = \log_{10} E_S$  with  $E_S$  in units of Joules. Yet, available instrumentation and analysis tools as well as simplifications introduced in the interest of mass routine measurements by technical personal resulted in the development of various regional K-scales which mostly do not measure  $(A/T)_{\max}$  (proportional to ground motion velocity) but displacement amplitudes A only. This, however, made in fact K to be a size estimator which is more closely related to Ml and for small to moderate size earthquakes also to Mw rather than being a good estimator of released seismic energy  $E_S$  or modern energy magnitude Me. An exception is the Kamchatka K, which is based on measuring  $(A/T)_{\max}$  (see Figure 5 in IS 3.7). Therefore, it scales also reasonably well with teleseismic Me based on the integration of squared velocity amplitudes on broadband records (see Figure 11 in IS 3.7).

Generally, there exist significant differences between the various local to regional K-scales, such as exist for any local-regional magnitude scale (see sections 3.2.4.3 to 3.2.4.5 for Ml, Md and mb(Lg)). This makes a simple and globally valid conversion of published K values into relevant magnitude equivalents impossible. For a very rough orientation, however, which K value would approximately correspond to a given “western” magnitude, or vice versa, Bormann derived, on the basis of a figure published by Riznichenko (1992) (see Figure 8 in IS 3.7), the following “conservative” formulas

$$\log E_S \approx K = 1.8 M + 4.1, \quad (3.30a)$$

or, when resolved for M,

$$M = 0.556 K - 2.3 \quad (3.30b)$$

where M, depending on distance and event size, is supposed to relate either to Ml (for values << 4 to about 6), mb (for > 4 to about 5.5), mB (between about 5.5 to 7.5) or Ms (> 6 to about 8.5).

However, according to Fig. 3.32, the Eqs.(3.30a) and (3.30b) generally estimates for a given

Mw a higher K than any of the other K or magnitudes scales, or, for a given K underestimates Mw or the respective other magnitude values.. The differences in K are smallest and in the range  $3 < Mw < 6.5$  almost negligible when calculating K according to the linear Rautian (1960) formula for Tadshikistan, which is practically identical with Eq. (3.30b).:

$$M = (M_L) = 0.56 K - 2.22. \quad (3.31)$$

Yet, when lowering in Eq.(3.30) K by about 1.5 units this would result in a better **average** M to K conversion estimate, although with a large average deviation in the order of 1 unit in K with respect to other specific regional conversion relationships.

**Fig. 3.32** Non-linear relationships between K-class, Mw, Ml and different kinds of P-wave magnitudes according to Figure 9 in IS 3.7, provided by A. Gusev, in comparison with the linear M-K relationship of Eq. (3.30). For explanation of legend and references see IS 3.7.

This is confirmed when comparing Eq. (3.31) with the linear regressions between K and short-period  $mb = Mb$  in Figure 7a of IS 3.7, however Eq. (3.31) is for the various linear K-Ms relationships a somewhat better average estimator (Fig. 3.33). Thus, one should be aware of the uncertainty of K to M and M to K conversions which depend on the type of magnitude and the sometimes large differences between the various regional K scales. The causes of these differences may not even be of pure seismological reasons, such as differences in prevailing source and wave propagation processes. E.g., the discrepancy between KF68 and KSol in Fig. 3.32 is mainly due to an error in the absolute scaling constant of KSol, which result in K values that are 0.6 units too low (Fedotov, 1972). Also assumptions made about the shear wave velocity for calculating the wave energy density on the reference sphere have been somewhat different, e.g., for the Rautian and Fedotov K scales (see related discussion in IS 3.7). Such inconsistencies in K procedures and scaling may significantly biases the seismological conclusions which could be drawn from the data and should be eliminated.

None the less, the authors of IS 3.7 see great potential for modernizing and homogenizing the K-class procedures with the aim to establish an empirically founded simple and very useful

energy-related complement to both teleseismic  $M_e$  as well as to local and regional  $M_L$ . Proper  $M_e$  calculations, which are chiefly based on model assumptions and full-fledged energy integration, are hardly possible on a mass routine basis and at the higher frequencies at which small to moderate local and regional earthquakes are recorded. On the other hand  $M_L$  is, in contrast to **what K is supposed to be**, more closely related to seismic moment and  $M_w$  than to **released seismic energy**. But, in order to bring up K to what it was originally intended for, it is necessary that future K is consistently calculated only on the basis of maximum measured ground motion velocity amplitudes  $V_{\max}$  instead of displacement amplitudes  $A_{\max}$ . And  $V_{\max}$  should be measured directly on standardized, in all regions compatible short-period records with identical (real or simulated) transfer functions that are velocity proportional in a sufficiently wide bandpass range that covers the expected corner frequencies of the source spectra of all earthquakes in the K or magnitude range of interest. Similarly, a unique model and elastic parameter set used for calculating energy density as well as the procedures for calibrating regional K-scales to a standard reference K-scale have to be developed, agreed upon and carefully documented, as they exist for standard ML (see 3.2.4.3). Otherwise, no interregional compatibility of K values can be achieved.

**Fig. 3.33** Linear orthogonal regression relationships between (a) ISC  $m_b = M_b$  and (b) ISC  $M_s = M_S$  with different regional K scales (according to Figure 7 in IS 3.7) and their

comparison with Eq. (3.31).

### 3.2.4.7 The Japanese $M_{JMA}$ scale

The Japan Meteorological Agency (JMA) uses routinely its own magnitude scale.  $M_{JMA}$  magnitudes are determined from the maximum ground displacement amplitude  $A$  of the total seismic event record trace and measured at any station at epicentral distance  $\Delta < 2000$  km. The maximum amplitude may be either that of a surface wave or of a body wave recorded by a seismograph with an eigenperiod of 5 s. According to Katsumata (1996) two calibration functions are used:

a) for earthquakes at focal depth  $h < 60$  km Tsuboi's (1954) formula, which is said to be well calibrated with the Gutenberg and Richter (1954) magnitudes. It reads

$$M_{JMA} = \log \sqrt{(A_N^2 + A_E^2)} + 1.73 \log \Delta - 0.83 \quad (3.32a)$$

where  $A_N$  and  $A_E$  are half of the maximum peak-to-trough amplitudes in  $\mu m$  with periods  $T \leq 10$  s in the two horizontal components and  $\Delta$  is given in km, and

b) for earthquakes deeper than 60 km Katsumata's (1964) formula

$$M_{JMA} = \log A + K \quad (3.32b)$$

where  $K$  is a function of  $\Delta$  and  $h$  and given as a table by Katsumata (1964). Also this formula was scaled so that it gives almost the same magnitude values as that of Gutenberg and Richter (1954). Both Koyama et al. (1982) and Nuttli (1985) give rather similar (average graphical) relationships between  $M_s$  and  $M_{JMA}$ . The agreement is almost perfect at magnitude 7, however  $M_{JMA}$  tends to be increasingly larger than  $M_s(20)$  for smaller magnitudes, up to about 1 m.u. at  $M_{JMA} = 5$ .

Interestingly, the Tsuboi formula (3.32a) was derived on the basis of records of the astatic medium-period Wiechert horizontal pendulum records (see *Dedication to Wiechert and Galitzin* via the NMSOP-2 cover page), which had a flat displacement response for periods between about 0.1 and 5 s. All later introduced instruments or simulation filter responses used for measuring  $M_{JMA}$  mimic approximately the original Wiechert response. However, for earthquakes with  $M_w < 5.5$  nowadays also velocity proportional responses, flat between about 1 and 30 Hz may be used for measuring an  $M_{JMA}(\text{velocity})$ . Further, station magnitudes that deviate from the average network magnitude more than 0.5 m.u. are not taken into account in calculating the event magnitudes and mean values of the latter with standard deviations  $\geq 0.35$  m.u. are not given as event magnitudes (personal communication by Yasuhiro Yoshida, 1996).

## 3.2.5 Common teleseismic magnitude scales (P. Bormann and S. Wendt)

Wave propagation in deeper parts of the Earth is, within a few percent of lateral velocity perturbations (see Chapter 2, Fig. 2.80), more regular than in the crust and can for most purposes be described sufficiently well by 1-D velocity and attenuation models. This permits derivation of globally applicable teleseismic magnitude scales. Fig. 3.34 shows smoothed  $A-\Delta$

relationships for short-period P and PKP waves as well as for long-period surface waves for teleseismic distances, normalized to a magnitude of 4.

**Fig. 3.34** Approximate smoothed amplitude-distance functions for P and PKP body waves (at about 1 Hz) and of long-period Rayleigh surface waves LR at periods  $T \approx 20$  s for an event of magnitude 4.

From Fig. 3.34 the following general conclusions can be drawn:

- Surface waves and body waves have a different geometric spreading and attenuation. While the former propagate in two dimensions only, with amplitudes  $A$  decaying with distance  $\Delta$  roughly  $\sim \sqrt{\Delta}$ , the latter propagate three-dimensionally, with amplitudes decaying in a homogeneous full space  $\sim \Delta$ . Therefore, for shallow seismic events of the same magnitude, surface waves have generally larger amplitudes than body waves.
- Surface wave amplitudes change smoothly with distance. They generally decay up to about  $140^\circ$  and increase again beyond about  $150^\circ$ - $160^\circ$ . The latter is due to the increased geometric focusing towards the antipodes of the spherical Earth's surface which then overwhelms the amplitude decay due to attenuation.
- In contrast to surface waves, the  $A$ - $\Delta$  relations for first arriving longitudinal waves (P and PKP) show significant amplitude variations. The latter are mainly caused by energy focusing and defocusing due to velocity discontinuities in deeper parts of the Earth. Thus the amplitude peaks at around  $20^\circ$  and  $40^\circ$  are related to discontinuities in the upper mantle at 410 km and 670 km depth, the rapid decay of short-period P-wave amplitudes beyond  $90^\circ$  is due to the strong velocity decrease at the core-mantle boundary (“core shadow”), and the amplitude peak for PKP near  $145^\circ$  is caused by the focusing effect of the outer core (see Fig. 11.59??).

Other body wave candidates for magnitude determinations again behave differently, e.g. PP which is reflected at the Earth's surface half way between the source and receiver. PP does not have a core shadow problem and is well observed up to antipode distances. Furthermore, one has to consider that body waves are generated efficiently by both shallow and deep earthquakes. This is not the case for surface waves. Accordingly, the different  $A$ - $\Delta$ - $h$  behavior

of surface and body waves requires different calibration functions if one wants to use them for magnitude determination.

### 3.2.5.1 Surface-wave magnitude scales $M_s$ and the new IASPEI standards

Gutenberg (1945a) developed the magnitude scale  $M_s$  for teleseismic surface waves:

$$M_s = \log A_{H_{\max}}(\Delta) + \sigma_s(\Delta). \quad (3.33)$$

It is based on measurements of the maximum horizontal ground motion displacement amplitudes  $A_{H_{\max}} = \sqrt{(A_N^2 + A_E^2)}$  of the surface wave train at “periods of about” 20 s although Gutenberg used occasionally also periods as low as 12 s and as high as 23 s (Abe, 1981a; Lienkaemper, 1984; see section 4.4 in IS 3.3). The surface-wave maximum usually corresponds to the Airy phase, a local minimum in the group velocity dispersion curve of Rayleigh surface waves which arises from the existence of a low-velocity layer in the upper mantle (see Fig. 2.10 in Chapter 2).

It should be noted, however, that according to Geller and Kanamori (1977) Gutenberg did not measure the true maximum horizontal motion vector with both components measured at the same time. Rather, he combined the largest amplitude in the  $A_N$  component with the largest amplitude of  $A_E$ , although they might occur at different time and belong to different types of surface waves (see Figure 5 in Section 4.4 of IS 3.3). There was no corresponding formula given for using vertical component surface waves, which would have avoided this problem, because no comparably sensitive and stable vertical component long-period seismographs were available at that time.

The calibration function  $\sigma_s(\Delta)$  is the inverse of a semi-empirically determined  $A$ - $\Delta$ -relationship scaled to an event of  $M_s = 0$ , thus compensating for the decay of amplitude with distance. The specified Gutenberg (1945a) formula, applicable between  $20^\circ \leq \Delta < 130^\circ$  epicentral distance, reads:

$$M_s = \log A + 1.656 \log \Delta^\circ + 1.818 \quad (3.34)$$

where  $\Delta^\circ$  is in degrees and  $A$  the ground motion displacement amplitudes in  $\mu\text{m}$ . Differences in the calibration term are  $<0.05$  m.u. as compared to respective tabulated calibration values published by Richter (1958) (see DS 3.1). The latter, however, account better than the simple formula for the energy focusing of surface waves towards the antipodes. The differences between  $M_s$  values calculated for distances  $>130^\circ$  according to (3.33) or by using the tabulated calibration values are 0.07 m.u. at  $140^\circ$ , 0.12 m.u. at  $160^\circ$  and 0.55 m.u. at  $180^\circ$ .

The Gutenberg relationship was further developed by Eastern European scientists. Soloviev (1955) proposed to use instead of the maximum ground displacement  $A_{\max}$  the maximum ground particle velocity  $V_{\max} = 2\pi(A/T)_{\max}$  since the latter is more closely related to seismic energy. Moreover,  $(A/T)_{\max}$  also better accounts for the large variability of periods at which surface-waves have their largest amplitudes, depending on distance of travel, crustal structure but also on magnitude and source depth, i.e., on the primary conditions of wave excitation. And finally, measuring  $(A/T)_{\max}$  permits rather stable magnitude estimates in a wider range of distances than the Gutenberg relationship which requires to read only periods around 20 s at teleseismic distances. Although for most continental Rayleigh waves the Airy phase periods

are around 10 to 15 s and for dominantly oceanic travel paths periods around 20 s and more (Bullen and Bolt, 1985; Marshall and Basham, 1972), the actual range of periods at which  $(A/T)_{\max}$  in the surface-wave trains is observed is much larger, ranging between  $2 \text{ s} < T < 60 \text{ s}$ . Periods, measured at the China Earthquake Network Center (CENC), have been plotted over epicenter distance  $\Delta$  in Fig. 3.35a and respective bulletin data prior to 1971 in Fig. 3.35b. Note the obvious distance trend of average  $T$  for  $\Delta < 70^\circ$ .

**Figure 3.35 a)** Variability of periods associated with  $V_{\max}$  of the Rayleigh wave group depending on distance  $\Delta$ . The gray shaded stripe marks the period range for which traditional  $M_s$  measurements at the U.S. Geological Survey's National Earthquake Information Center (NEIC) are carried out. Light gray columns give the observed range of average periods as published by Vaněk et al. (1962) and Willmore (1979), and the stars give the respective average periods of the plotted open circle data points within the related magnitude segment. Copy of Figure 8 in Bormann et al. (2009), p. 1874, © Seismological Society of America.

**b)** 3-component distance-period plots for  $(A/T)_{\max}$  surface wave readings retrieved at the ISC from printed station/network bulletins for earthquakes that occurred before 1971 and for stations shown in Figure 7 of Di Giacomo et al. (2013a). Figure by courtesy of Di Giacomo, 2013.

Based on early observations of this kind Soloviev and Shebalin (1957) and Karnik (1956), a team of researchers from Moscow and Prague proposed a new  $M_s$  scale and calibration function (Karnik et al., 1962 ; Vanek et al., 1962):

$$M_s = \log (A/T)_{\max} + \sigma_s (\Delta) = \log (A/T)_{\max} + 1.66 \log \Delta + 3.3. \quad (3.35)$$

It is applicable at epicentral distances  $2^\circ < \Delta < 160^\circ$ , for sources that are less than 60 km deep and to surface-wave amplitude readings with periods above 3 s. The IASPEI Committee on Magnitudes recommended at its Zürich meeting in 1967 the use of “the Moscow-Prague 1962 formula” as **standard for  $M_s$  determination**.

The recommendation to use the Prague formula as standard for  $M_s$  calculation has generally been accepted by the global seismological community. However, as outlined by Bormann et al. (2009), there have been widespread misunderstanding and wrong statements in publications by other authors about how and in which ranges of distance and periods this formula should be used. No wonder that the concerned U.S. agencies decided to use it only at teleseismic distances and for amplitude readings in the period range 18s to 22 s in keeping with Gutenberg’s original formula and recommendations. This, however, made the deliberate introduction of  $(A/T)_{\max}$  in the Prague formula practically meaningless, because differences in period readings in this narrow period range make for less than 0.1 m.u. difference. Yet, this U.S. practice, based on amplitude readings on records of the long-period WWSSN-LP instrument (see response in Fig. 3.20), became standard throughout the western seismological community.

In contrast, seismological observatories in the former Soviet Union (FSU) and its allied countries used formula (3.35), as recommended in the original publications and in the Willmore (1979) Manual of Seismological Practice. And A and T values were read on records of type Kirnos seismographs with displacement proportional response between about 0.1 and 10 to 20 s (see response Fig. 3.20), as most of the earlier data readings which had led to the derivation of the Prague formula.

In China, however,  $M_s$  values were routinely determined according to both  $M_s$  concepts. This provided to the IASPEI/CoSOI WG on Magnitudes a unique opportunity to compare the respective data measured on the same stations of the China National Seismic Network and analyzed by the same personnel at the China Earthquake Network Center (CENC). The results, published by Bormann et al. (2007), revealed both similarities and relevant differences of the respective  $M_s$  values and encouraged the WG to propose the following two **IASPEI standards for  $M_s$**  (see IASPEI 2005 and its updates of 20011 and 2013):

$M_s(20)$ , or  $M_{s\_20}$  in the ISF format (see Chapter 10) for data exchange and archiving, and  $M_s(BB)$ , or  $M_{s\_BB}$ , respectively. Their abridged definitions read as follows (for more details see IS 3.3):

$$M_{s\_20} = \log_{10}(A/T) + 1.66\log_{10}\Delta + 0.3, \quad (3.36)$$

“where  $A$  = **vertical-component** ground displacement in **nm** measured from the maximum trace-amplitude of a surface-wave phase having a period between **18 s and 22 s** on a waveform that has been filtered so that the frequency response of the seismograph/filter system replicates that of a World-Wide Standardized Seismograph Network (WWSSN) **long-period seismograph** ... with  $A$  being determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-LP response at period  $T$ ,  $\Delta$  = **epicentral** distance in degrees,  $20^\circ \leq \Delta \leq 160^\circ$ ”.

Equation (3.36) is formally equivalent to the  $M_s$  equation proposed by Vaněk et al. (1962) but is here applied to vertical motion measurements in a narrow range of periods. Moreover,  $M_{s\_20}$  is expected to significantly underrepresent the energy released by intermediate- and deep-focus earthquakes due to their less effective generation of 20 s surface waves. Therefore, some agencies generally compute  $M_{s\_20}$  only for shallow-focus earthquakes, typically those whose confidence-intervals on focal-depth would allow them to be shallower than 50 or 60 km. For deeper earthquakes adjustment would need to be made, e.g., in accordance with Herak et al. (2001) (see also Question 4 below) in order to assure compatibility of  $M_{s\_20}$  data within the acceptable uncertainty limit of about 0.1 m.u. for IASPEI standard magnitudes.

For  $M_{s\_BB}$  the standard formula reads:

$$M_{s\_BB} = \log_{10}(V_{\max}/2\pi) + 1.66 \log_{10}\Delta + 0.3, \quad (3.37)$$

“where  $V_{\max}$  = ground **velocity in nm/s** associated with the maximum trace-amplitude in the surface-wave train, as recorded on a **vertical-component** seismogram that is **proportional to velocity**, where the period of the surface-wave,  $T$ , should satisfy the condition  $3 \text{ s} < T < 60 \text{ s}$ , and where  $T$  should be preserved together with  $V_{\max}$  in bulletin data-bases;  $\Delta$  = **epicentral** distance in degrees,  $2^\circ \leq \Delta \leq 160^\circ$ ”

Formula (3.37) is based on the  $M_s$  equation proposed by Vaněk et al. (1962), but is here applied to vertical motion measurements and is used with the  $\log_{10}(V_{\max}/2\pi)$  term replacing the  $\log_{10}(A/T)_{\max}$  term of the original. (3.37) could be further simplified by including  $-\log_{10}2\pi = -0.8$  into the constant, thus sparing one operation and reading

$$M_{s\_BB} = \log_{10}V_{\max} + 1.66 \log_{10}\Delta - 0.5. \quad (3.37a)$$

Also  $M_{s\_BB}$  should be calculated for shallow focus earthquakes only, unless appropriate depth corrections are made (see Question 4 below).

As of now (2012), both the ISC and NEIC use Eq. (3.36) for the determination of  $M_s$  from events with focal depth  $h < 60$  km without specifying the type of waves or components considered. The ISC accepts both vertical or resultant horizontal amplitudes of surface waves, with periods between 10 - 60 s from stations in the distance range  $5^\circ - 160^\circ$  but calculated the representative average  $M_s$  only from observations between  $20^\circ - 160^\circ$ . In contrast, the NEIC calculated so far only  $M_{s\_20}$  from vertical component readings of stations between  $20^\circ \leq \Delta \leq 160^\circ$  and for reported periods of  $18 \text{ s} \leq T \leq 22 \text{ s}$ . This limitation in period range is not necessary and limits the possibility of  $M_s$  determinations from weaker and regional earthquakes.

Recently, there has been again a tendency to determine the surface-wave magnitude by specifying the type of the waves and/or components used, e.g., MLRH or MLRV from

Rayleigh waves and MLQH from Love waves or simply MLH and MLV as was the practice in Eastern Germany in the 1960's (see Tab. 3.1) and recommended already in 1967 by the IASPEI Committee on Magnitude at Zürich. Since the newly proposed IASPEI Seismic Format (see 10.2.5) accepts such specifications (in the case that they require more than 5 characters in the metadata reported to data centers), the IASPEI WG on Magnitudes intends to elaborate recommendations for unambiguous standards and “specific” magnitude names. For a preliminary version see IS 3.2.

**Question 1: Are the new IASPEI Ms standards compatible with Gutenberg Ms?**

For 20 s surface waves of the same amplitudes Eqs. (3.35) and (3.36) yield about 0.18 m.u. (0.19 m.u. at  $\Delta = 100^\circ$ ) units larger Ms values than the original Gutenberg formula (3.34). Therefore, Abe (1981a) gave the following relationship between Ms determinations by NEIC using Eq. (3.35) and  $M_{GR}$  values published by Gutenberg and Richter (1954):

$$Ms(\text{“Prague”}, \text{NEIC}) = M_{GR}(\text{Gutenberg-Richter}) + 0.18. \quad (3.38)$$

This conclusion, however, could **not be confirmed** by Lienkaemper (1984). Recomputations with the Moscow-Prague formula for the same events were only 0.03 m.u. higher on average than  $M_{GR}$ . In section 4.4 of IS 3.3, Bormann and Dewey give additional reasons for the good agreement. Moreover, Bormann et al. (2009) compared  $Ms(\text{NEIC})$  with strict  $Ms_{20}$  determinations and found an excellent agreement (Fig. 3.36). Thus the **compatibility with earliest available and future Ms determinations at periods around 20 s is quantitatively assured** despite several changes in instrumentation and in the procedure of reading amplitudes on horizontal and later vertical-component recordings.

**Fig. 3.36** Data and linear regression relations (standard and orthogonal) between the new IASPEI standard  $M_s_{20}$ , measured at the China Earthquake Network Centre (CENC) by using China network data alone for earthquakes in the years 2001-2007, and the respective event  $M_s$ (NEIC) based on global data.  $R_{XY}$  – correlation coefficient;  $RMSO$  – orthogonal rms error, based on data published in Bormann et al. (2009).

NEIC never measured  $M_s$  in a wider range of period and distance. Therefore, a similar comparison cannot be made with  $M_s_{BB}$ . But Fig. 3.37 shows an excellent overall correlation between  $M_s_{20}$  and  $M_s_{BB}$ , yet with a slight systematic difference in trend: For magnitudes less than about 6.5  $M_s_{BB}$  tends to be increasingly larger, reaching on average 0.3 m.u. at  $M_s_{BB} = 4.5$  (Fig. 3.37). The main reason is that the average period at which the surface waves have their largest  $V_{max}$ , respectively  $(A/T)_{max}$ , depends also on magnitude, dropping from about 16 s at  $M_s_{BB} = 6.5$  down to about 11 s at  $M_s_{BB} = 4.5$ , i.e., well below the 18 to 22 s period range at which  $M_s_{20}$  is measured (see Figure 7 in Bormann et al., 2009). Accordingly, at  $T = 11$  s the ratio  $A/T$  is twice as large as at  $T = 22$  s. This makes for a difference of 0.3 m.u.

**Fig. 3.37** Data and linear regression relations (standard and orthogonal) between the new IASPEI standard magnitudes  $M_s_{20}$  and  $M_s_{BB}$ , measured at CENC.  $R_{XY}$  = correlation coefficient,  $RMSO$  = orthogonal root mean square error. Figure compiled from data published in Bormann et al. (2009).

Figure 7 in IS 3.3 illustrates how in general (although not in each single case) the difference between  $M_s(BB)$  and  $M_s(20)$  grows with growing deviation of the periods at which  $V_{max}$  is measured in BB records from the narrow period range of  $M_s_{20}$ . Since surface waves of weaker earthquakes are recorded only at shorter distances with dominatingly shorter periods this magnitude dependence on the measured surface-wave periods translates also into a

distance dependence (see Fig. 3.35). One consequence is that  $M_s$ \_20 data systematically underestimate  $M_w$  at magnitudes below about 6.5 at which energy is systematically radiated at shorter periods than 20s (see Fig. 3.5 right; Kanamori and Anderson, 1975; Ekström and Dziewonsky, 1988). The then larger  $M_s$ \_BB values reduce this difference by almost 50% (Fig. 3.38).

While Ekström and Dziewonsky (1988) consider the significant slope change in the relationship between  $M_w$  and  $M_s = M_s$ \_20 for  $M_w <$  about 6.5 as an  $M_s$  bias in estimating earthquake size, others (J. Dewey, personal communication 2013) are even inclined to consider this as an advantage of  $M_s$ \_20, because then, in the range  $M_w \approx 4.5$  to 6.5,  $M_s$  is approximately proportional to  $\log M_0$ . However, as long as  $M_w$  is officially considered as being **the authoritative magnitude** that best represents earthquake size, even down to negative magnitudes (see, e.g., Kwiatek et al., 2010), and not  $M_s$  because of its near one-to-one relationship with  $\log M_0$  in a limited magnitude range, it is preferably to judge the earthquake size representativeness of other magnitude scales with respect to their relationship to  $M_w$  and not to  $M_s$  or  $\log M_0$ . When accepting this argument, then  $M_s$ \_BB is from all very easy to measure classical magnitudes the one which differs on average least from  $M_w$  ( $\leq 0.3$  m.u., Fig. 3.38) in the wide magnitude range from about  $M_w$  4.5 to 8.5. In contrast, the deviations are  $\leq 0.5$  m.u. for  $mB$ \_BB (see Fig 3.74 and Fig. 3.79 upper right), may reach about 0.6 m.u. or even more for  $M_s$ \_20 (Figs. 3.70a, 3.79 lower left, 3.81), 1.0 m.u. for  $ML$  and 1.0 -1.5 for  $mb$  (see Utsu, 2002, Fig. 3.70a; and for  $mb$  also Fig. 3.79 upper left and Fig. 3.81).

Moreover,  **$M_s$ \_BB**, is in tune with the  $M_s$  standard calibration equation (3.35), permits  $M_s$  determination down to epicentral distances of only  $2^\circ$  and tends to have smaller measurement errors than  $M_s$ \_20, both when measured interactively (Table 5 in IS 3.3) or in automatic mode (Tab. 3.2 and Figs. 3.25 and 3.26). Thus,  **$M_s$ \_BB** is a robust surface-wave magnitude which yields in some distance and magnitude ranges **valuable complementary information to  $M_s$ \_20**.

**Fig. 3.38** Data and linear regressions between the new IASPEI standard  $M_s$ \_BB, measured at CENC, and  $M_w$ (GCMT) as well as the approximate respective regression line of  $M_s$ \_20 for  $M_w < 6.5$ . Figure compiled according to data published in Bormann et al. (2009).

**Question 2: *Is  $M_s$  measured on horizontal and vertical components compatible?***

The calibration terms in both the Gutenberg and the Moscow-Prague formula for  $M_s$  determination had been derived for the correction of amplitude readings in horizontal (H) component records only. The introduction of stable long-period vertical component (V) seismometers into global seismological practice in the 1960s introduced another change in  $M_s$  measurement practice. According to Hunter (1972) the differences between  $M_s(V)$  and  $M_s(H)$  are negligible. This was confirmed by Bormann and Wylegalla (1975). According to their orthogonal regression relationship

$$MLV = 0.97MLH + 0.19, \quad (3.39)$$

with a correlation coefficient of 0.98 and a standard deviation of  $\pm 0.11$  m.u. only, the two magnitudes differ on average in the magnitude range between 4 to 8.5 less than 0.07 m.u. Thus, both findings **confirm the continuity and compatibility of old and modern  $M_s$  data**. Therefore, from May 1975 onwards, the USGS decided to calculate their  $M_s$  exclusively from vertical component readings. Since that time,  $M_s$ (NEIC) is in fact identical with the IASPEI confirmed standard magnitude  $M_s$ \_20.

**Question 3: *How reliably do the calibration formulas for  $M_s$  determination compensate for the distance dependence of amplitudes?***

Both the original Gutenberg relationship (3.33) and the Moscow-Prague IASPEI standard relationship (3.35) are rather simple and supposed to be used up to  $140^\circ$ , respectively  $160^\circ$  epicentral distance only. Reason: Both simple formulas do not well account for the amplitude increase beyond  $140^\circ$  due to the focusing of surface-waves near the antipode (see Fig. 3.34). This, however, can be avoided by using the respective tabulated calibration values instead (see DS 3.1., Tables 3 and 4). For  $M_s$ \_BB determination the tabulated Moscow-Prague calibration values agree at epicentral distances between  $1^\circ$  and  $140^\circ$  within 0.05 magnitude units with the values calculated from the calibration term in formula (3.35). For larger distances, however, this formula overestimates the magnitude between 0.05 and 0.55 (at  $180^\circ$ ) m.u. About the same applies when comparing values calculated with the Gutenberg formula (3.33) with the related tabulated calibration values published by Richter (1958). Therefore, **preference should be given to the use of the tabulated values, at least for distances  $>140^\circ$** .

However, several authors realized that using standard formula (3.35) for calculating 20 s  $M_s$  results in systematic distance-dependent biases (von Seggern, 1977; Herak and Herak, 1993; Rezapour and Pearce, 1998). Therefore, they proposed revised formulas for  $M_s$ \_20 calculation. The revised formula of Herak and Herak for  $M_s$ \_20 is:

$$M_s = \log (A/T)_{\max} + 1.094 \log \Delta + 4.429. \quad (3.40)$$

It is based on USGS data, i.e., on amplitude readings in the period range 18 to 22 s. It provides distance-independent estimates of  $M_s$  over the whole distance range  $4^\circ < \Delta < 180^\circ$ .  $M_s$  values according to Eq. (3.40) are equal to those from Eq. (3.35) at  $\Delta = 100^\circ$ , larger by 0.39 magnitude units at  $\Delta = 20^\circ$  and smaller by 0.12 units for  $\Delta = 160^\circ$ . Eq. (3.40) is practically equal to the formulae earlier proposed by von Seggern (1977) and similar to the more recent formula (18) obtained by Rezapour and Pearce (1998) on the basis of all ISC  $M_s$  data between 1978 and 1993:

$$M_s = \log (A/T)_{\max} + 1/3 \log(\Delta) + 1/2 \log(\sin\Delta) + 0.0046\Delta + 5.370. \quad (3.41)$$

Formula (3.41) makes allowance for the theoretically known contribution of both dispersion and the distance-dependent geometrical spreading, thus providing an improved overall distance correction, especially beyond  $\Delta = 145^\circ$  and reduces for intermediate size earthquakes the scatter against  $\log M_0$  as compared to  $M_{s\_20}$  calculated with the Moscow-Prague formula.

Developing new calibration formulas for  $M_{s\_20}$  is principally correct, because the IASPEI standard Moscow-Prague formula had not been developed for calibrating displacement amplitudes at periods around 20 s but for calibrating  $(A/T)_{\max}$  in a much wider range of periods and distances. Already Gutenberg (1945a) wrote in his  $M_s$  paper, that the 20 s condition “is not fulfilled for distances less than  $20^\circ$ .” Therefore, reported distance-dependent biases may reach at near regional distances up to about 0.5 m.u. and are in perfect agreement with the observed trend to shorter surface-wave periods as presented in Fig. 3.35, whereas for stronger earthquakes recorded at larger distances the difference between  $M_{s\_20}$  and  $M_{s\_BB}$  is in most cases negligible (Fig. 3.37). Yet, with the exception of formula (18) in Rezapour and Pearce (1998), which has become the standard  $M_s$  formula at the International Data Center (IDC) of the CTBTO (see Chapter 15), none of these alternative  $M_{s\_20}$  calibration relationships has already been accepted as a global standard. However, there is a need for it and it will surely reduce the currently existing systematic difference between  $M_{s\_20}$  and  $M_{s\_BB}$  in certain distance and magnitude ranges. There is hope that the now beginning global collection of standardized  $M_{s\_20}$  data with likely reduced procedure-dependent errors will finally result in a globally accepted new calibration function for standard  $M_{s\_20}$ .

#### **Question 4: Why is there no depth term in the $M_s$ calibration functions?**

The amplitudes of the fundamental surface-wave mode decay exponentially with depth (see Chapter 2) and routine depth determinations for shallow earthquakes ( $< 70$  km) are still rather uncertain (at present with errors in the order of 10-20 km, at Gutenberg’s time even worse or undetermined). This limited both the derivation and the meaningful application of depth corrections. On the other hand, more than 95% of the global seismic moment is released by shallow earthquakes. Therefore, Gutenberg (1945a) proposed to use his formula only for earthquakes at source depths not exceeding 40 km and to use only surface waves around 20 s which are also less sensitive to uncertainties in source depth than those with shorter periods. He even specified: “...it seems that for shocks with a depth of focus of about 35 km, 0.1 should be added to the magnitude calculated from (1) [here Eq. (3.33)] to bring the resulting  $M$  into agreement with the original zero point of Richter’s scale, and that the values given in table 4 are not affected by more than  $\pm 0.2$  by variations in focal depth so long as this does not exceed 40 km.” And in Gutenberg (1945b) he even wrote: “The determination of the magnitude of shocks with a focal depth in excess of about 30 km must be based on the

*amplitudes of the body waves*". Theoretical calculations by Panza et al. (1989) indicate that the depth correction may already exceed 1 m.u. even for shallow sources. This is confirmed by an empirical formula of Ochozinskaya (1974) used at seismic stations in Russia for determining the depth of shallow earthquakes ( $h < 70$  km) from the relationship between  $m_B$  and  $M_s$ :  $h(\text{in km}) = 54m_B - 34M_s - 107$  with a correlation coefficient of 0.88. For the same reasons also Vaněk et al. (1962) did not include depth corrections in their formula but relaxed somewhat the upper depth limit being aware of the uncertainties both of the initial hypocenter depth determinations and their limited relevance with respect to the hypocenter position of maximum seismic energy release in the case of large finite source ruptures.

#### **Question 5: Are depth correction terms for $M_s$ available and feasible?**

Empirically derived corrections for intermediate and deep earthquakes were published by Båth (1985). They range between 0.1 and 0.5 magnitude units for focal depths of 50 - 100 km and between 0.5 and 0.7 units for depths of 100 - 700 km. Based on model calculation and their comparison with real observations of 20 s surface waves from earthquakes down to  $h = 530$  km depth, Herak et al. (2001) proposed the following corrections  $\Delta M_s(h)$  for 20 s surface waves, which are in the same range as the empirical data by Båth (1985), i.e., up to about 0.75 m.u. near 600 km depth (see also Fig. 3.39):

$$\begin{aligned} \Delta M_s(h) &= 0 & \text{for } h < 20 \text{ km} & \quad (3.42) \\ \Delta M_s(h) &= 0.314 \log(h) - 0.409 & \text{for } 20 \text{ km} \leq h < 60 \text{ km} \\ \Delta M_s(h) &= 1.351 \log(h) - 2.253 & \text{for } 60 \text{ km} \leq h < 100 \text{ km} \\ \Delta M_s(h) &= 0.400 \log(h) - 0.350 & \text{for } 100 \text{ km} \leq h < 600 \text{ km}. \end{aligned}$$

It would be desirable to test the feasibility of these correction terms globally based on type IAMs\_20 amplitude readings also for deeper earthquakes, maybe put in brackets, and to investigate their compatibility with  $m_b$ ,  $m_B$  and  $M_w$  estimates for these earthquakes. If such comparisons demonstrate the reliability, stability and thus feasibility of these depth corrections for  $M_s$  they may in future be integrated in a new  $M_s$ \_20 standard.

If  $V_{\max}$  is also found at periods around 20 s, than the Herak et al. (2001) corrections could be applied to  $M_s\_BB$  as well. However, the penetration depth of surface waves and therefore also the efficiency of surface-wave excitation depends on wavelength and thus period. If  $V_{\max}$  is measured at  $T \gg 20$  s (up to about 60 s) depth corrections may not be needed for source depth up to about 100 km. For periods of only about 5 s, however, the underestimation may become significant already for source depth larger than about 10 km. Regrettably, period-dependent source-depth correction terms have not yet been derived. With standard  $V_{\max}$  and related period data expected to become available en mass in future in the bulletins of international data centers it should be possible to determine such period-dependent empirical corrections in relation to those for  $M_s\_20$ .

**Question 6: How does travel paths affect the period at which  $M_s\_BB$  is measured?**

Marshall and Basham (1972) investigated how much the travel paths of Rayleigh (LR) surface waves affect their measured displacement amplitudes at different periods. They found “...that for an impulsive input into a North American path the amplitudes at 10 secs are eight times larger than the amplitudes at 20 seconds, due to the dispersion characteristics of the path alone;...” In contrast: “...over a Eurasian path the amplitude difference between 10 and 20 seconds is only a factor of two. The predicted amplitude at 20 seconds period for both paths is however almost equal, ...” Moreover they showed that both oceanic and mixed intercontinental paths LR waves exhibit relatively low amplitudes at the shorter periods below 20 s, yet, for  $20 \text{ s} < T < 45 \text{ s}$  oceanic path LR amplitudes dominate those with continental or mixed intercontinental paths. Therefore, the periods at which the largest LR velocity amplitudes were measured at stations of the China National Seismic Network (CNSN) up to epicenter distance of  $100^\circ$  on LR waves with dominantly continental or mixed paths were in 79% of the cases outside of the 18-22 s period band at which  $M_s\_20$  is measured (see Fig. 3.35). In contrast,  $M_s\_BB$  determined at stations of the German Regional Seismic Network (GRSN) up to  $D = 160^\circ$ , which include a larger share of LR of mixed or even dominantly oceanic paths than in records of the CNSN, “only” 62% of the  $LR_{\max}$  were measured at periods outside of the 18-22 s range, again being mostly shorter but with a larger share of  $T > 22$  s, up to 62 s (see Fig. 3.40).

**Fig. 3.40** Difference between  $M_s\_BB$  and  $M_s\_20$  in relation to the period at which  $V_{max}$  was measured on velocity broadband records at GRSN stations in Germany.

Figs. 3.41 shows for different source locations, magnitude ranges and paths the periods at which LR  $V_{max}$  has been measured with  $T < 35$  s at station CLL of the GRSN and Fig. 3.42 for some average regional paths LR  $V_{max}$  measured at even longer periods up to 60 s.

**Fig. 3.41** Periods at which  $V_{max}$  of LR waves has been measured on velocity broadband records at station CLL, Germany, depending on source location, event  $M_s$  and travel path.

**Fig. 3.42** Periods between 30 s and 60 s at which  $V_{\max}$  of LR waves has been measured on velocity broadband records at station CLL, Germany, along some prevailing average regional paths.

From Fig. 3.41 it is obvious that the periods at which  $V_{\max}$  is measured are:

- Generally less than 18 s for pure Eurasian path up to about 80° long, and mostly even shorter (between some 6 to 14 s) for distances less than 30-50°, also when travelling through the African continent via the Mediterranean Sea to Central Europe;
- Mixed Rayleigh-wave paths arriving from comparable backazimuth, e.g., New Zealand, travelling through about half oceanic and half Eurasian continental crust, have already periods between 22 and 26 s.
- Mixed path intercontinental LR travelling from the western coasts of South America, Central America or North America, respectively, to Central Europe have typically periods between 18-22s, 22-26 s (more oceanic) and 14-18 s, respectively;
- Periods longer than 26 s have been measured for some individual earthquakes with either dominating oceanic paths or even for mixed paths, e.g. for the slow 17 July 2006 Mw7.7 Java tsunami earthquake (red dot in Fig. 3.41), whereas from other, faster rupturing earthquakes in the same region (green dots)  $LR_{\max}$  is often recorded at periods between 14 and 18 s.

Interesting in Fig. 3.42 is the rather different and somehow unexpected behavior of the even more long-period LR and mantle Rayleigh waves with periods between 30 s and 60 s. Practically all paths from the relevant source regions are mixed paths to CLL station. The shortest periods between 30 s and 35 s may occur along both the shortest as well as the longest paths. And the longest periods, up to about 60 s, have been measured for mantle Rayleigh wave maxima arriving on the long teleseismic mixed path from SE Asia (e.g., off-coast Papua New Guinea earthquake).

#### ***Question 7: Why does the IASPEI Ms formula not include a period dependence?***

Since Gutenberg restricted the use of his empirically determined  $M_s$  formula to amplitude readings around 20 s, for which according to the later finding by Marshall and Basham (1972) there is also the best agreement between the maximum LR amplitudes for different continental and mixed paths, there was no need for introducing a period-dependent attenuation term.

The situation, however, is different for  $M_{s\_BB}$  which is measured at periods  $3\text{ s} < T < 60\text{ s}$ . Although attenuation losses for periods  $> 20\text{ s}$  may become increasingly negligible, this is not the case for much shorter period. Yet, interestingly, the empirical data collected by Soloviev and Shebalin (1956) and Karnik (1957) revealed a much higher stability of the read velocity amplitudes - or ratio  $(A/T)_{\max}$  - as compared to the respective displacement amplitudes, in a wide period range and still a high overall compatibility of their data with Gutenberg's  $M_s$ . And since the authors of the Moscow-Prague formula, in the interest of best possible data continuity, scaled their data to the Gutenberg relationship they neither investigated nor introduced a period-dependence in their formula.

Ambraseys (1985) confirmed the stability and broad applicability of Moscow-Prague formula (3.35) when applied to European recordings of medium-period instruments at distances  $\geq 4^\circ$ . Quote: *The data available from Northwestern European earthquakes of the last 70 years recorded mainly by light and heavy Wiecherts, Galitzin, Mainka, Quervain-Picard, Milne-Shaw, Grenet and modern medium-period instruments, suggest that on the average for  $D \geq 4^\circ$ ,  $M$  values calculated from equation (1) [here Eq. (3.35)] do not exhibit an unequivocal distance dependence. ... The fit does not improve if we include distance and path corrections following, say, Marshall and Basham. ... Consequently, equation (1) was used over any distance and without any restriction for measurements to a fixed period other than the restrictions imposed on  $D$  and  $T$  by the data proper. ... neither a period constraint nor distance effects for the regional conditions considered seem to play an important role.*"

Also Okal (1989) came to the conclusion that the use of  $(A/T)$  in the Moscow-Prague calibration formula is a **partial and ad hoc compensation** for a large number of frequency-dependent terms ignored by it. The simplest explanation is that attenuation terms which linearly increase with frequency are compensated by multiplying  $A$  with  $f = 1/T$ . When looking at the tremendous range of period variations in Fig. 3.35 at which surface wave  $V_{\max}$  has been measured by seismic stations at distances between  $2^\circ$  and  $100^\circ$  one can hardly believe that they yielded the stable and with  $M_{S\_20}$  generally compatible  $M_{S\_BB}$  data plotted in Fig. 3.37, and this with even slightly smaller average standard deviation than for  $M_{S\_20}$  data (see Table 5 in IS 3.3).

How much  $(A/T)_{\max} = V\pi/2\pi$  readings may stabilized the  $M_S$  estimate has been illustrated by Bormann et al. (2009) with an example observed at the German Regional Seismic Network:

*05 Feb. 2006, Alaska, average network  $\Delta \approx 61^\circ$ , 15-station network  $M_S(BB) = 4.91 \pm 0.08$  at average network  $T = 15.4 \pm 8.3$  sec, station BFO  $M_S(BB) = 5.0$  at  $T = 7.1$  sec, station CLZ  $M_S(BB) = 4.9$  at  $T = 28.6$  sec, i.e., within 0.1 unit the same  $M_S(BB)$  despite  $T_{CLZ} \approx 4 \times T_{BFO}$ .*

Moreover, Ambraseys (1985) also found, that medium-period  $(A/T)_{\max}$   $M_S$  data correlate well with local magnitudes estimated by a number of European stations. This has been confirmed by S. Wendt for  $M_{S\_BB}$  data of station CLL too.

Yet, the phrasing "partial" compensation by Okal (1989) may be reason enough to look closer into the need – or not – of introducing for different seismotectonic environments, especially in the regional distance range, frequency-, path- and/or distance-dependent corrections into the current standard  $M_{S\_BB}$  formula (3.37). Mass data of standard  $M_{S\_BB}$ , expected to become available in future together with the periods at which  $V_{\max}$  has been measured, would be ideal for such studies.

#### **Question 8: Exist $M_S$ scales with a frequency-dependent calibration term?**

Yes, they do. E.g., Yacoub (1998) presented a method for accurate estimation of Rayleigh-wave spectral magnitudes  $M_R$  by velocity and frequency window analysis of digital records. He applied it to records of underground nuclear explosions in the distance range  $5^\circ$  to  $110^\circ$  and compared  $M_R$  with the classical time-window magnitude estimates,  $M_S$ , according to Eq. (3.35). While **both agreed well**, in general  $M_R$  had smaller standard deviations. Another

advantage is that the procedure for  $M_R$  determination can easily be implemented for on-line automated magnitude measurements.

More recently, Bonner et al. (2006) reported about the application of their time-domain variable-period surface-wave magnitude measurement procedure at regional and teleseismic distances. It is based on multi-bandpass filtering in the period range from 8 to 24 s in increments of 4 s, selecting the maximum bandpass amplitude and correcting it with a period-dependent correction term. Yet, also these authors found a generally good agreement of their  $M_s(VMAX)$ , on average better than 0.1 m.u., with the formulas of Rezapour and Pearce (1998) and Vaněk et al. (1962) when applied at teleseismic distances, with the exception of a small distance-dependent trend of  $-0.002$  m.u./° and a standard deviation of 0.21 m.u. of carefully measured station magnitudes for a subset of 33 events from the Mediterranean region.

Yet, Bormann et al. (2009) got similar results for  $M_s\_BB$  with almost negligible differences when plotting for a much larger global event set and routine station readings the difference between  $M_s(BB)$  and  $M_s(NEIC)$  for earthquakes at depth  $h < 60$  km over the distance range  $2^\circ$  to  $103^\circ$ . When considering all measured periods of  $V_{max}$  in the range 3 s to 30 s (as compared to the 8-24 s data of Bonner et al.) the standard deviation of 0.33 m.u. and distance-dependent trend of  $-0.0029$  m.u./° were only somewhat larger. However, when using only periods  $< 15$  s in the whole distance range, for which larger attenuation effects would be expected, then the trend even reduced to merely  $-0.0009$  m.u./° and the standard deviation to 0.29 m.u.

Therefore, for the time being, all these comparisons still question the practical relevance of introducing frequency-dependent corrections in the  $M_s$  formulas in view of the generally large data scatter due to station site effects depending also on epicentral distance and backazimuth (see Question 9 on focusing and defocusing of LR waves). Probably the largest positive effect of the multi-bandpass filtering prior to  $M_s(VMAX)$  measurement for periods  $> 8$  s is, when compared with readings on unfiltered broadband records, that on stormy days ocean microseisms are strongly reduced and thus the SNR improved. This surely will reduce the standard deviation of  $M_s$  measurements. Since NEIC is now routinely calculating both  $M_s\_BB$  and  $M_s(VMAX)$  there may in future be more and better data available to assess the relative performance of these two kinds of variable frequency  $M_s$  procedures in different ranges of distance, backazimuth and source depth. This may help to decide about the necessity of introducing frequency-dependent attenuation terms also in the  $M_s\_BB$  formula. Maybe, the frequency-dependence of the quality factor  $Q$ , which we discuss below in conjunction with P-wave periods below 5 s, is another reason, why also surface-wave amplitudes measured at periods larger than 3 s for  $M_s\_BB$  or 8 s for  $M_s(VMAX)$  are less affected by attenuation towards shorter periods than expected from frequency-independent  $Q$  models. If this can be proved then no urgent need may be felt for introducing frequency-dependent attenuation corrections in the standard formula for  $M_s\_BB$  as long as the dominating station site and non-attenuative path effects due to unconsidered lateral velocity anomalies remain uncorrected.

#### ***Question 9: How do lateral velocity inhomogeneities affect the $M_s$ estimates?***

There may be significant regional and also station residual biases due to surface-wave path effects. Lateral velocity variations in the crust and upper mantle as well as refraction at plate

boundaries may result in significant focusing and de-focusing effects and thus regional over- or underestimation of station  $M_s$  or regional  $M_s$  averages as compared to global  $M_s$  event averages (Lazareva and Yanovskaya, 1975; Yanovskaya, 2012; Figs. 3.43, 3.44 a and b).

This is confirmed by comparing  $M_s$ \_BB measured at Collm (CLL) station in Germany with global  $M_s$ (NEIC) event averages (Fig. 3.44a). The  $M_s$ -residuals of CLL have been plotted over epicenter distance  $D$ . They show both a positive trend with growing distance as well as oscillations with average amplitudes up to +0.55 m.u. and individual data scatter up to more than one m.u. The large scatter also hints to another dependence on the backazimuth BAZ of the source region. This is confirmed by Fig. 3.44b when comparing the different average  $M_s$  residuals from the Kamchatka, Kuriles and Japan source region with those from SW North America, Central America and NW South America, all being about the same epicentral distance  $D \approx 85^\circ$  away from CLL but mostly with smaller and even negative residuals.

Relating  $M_s$  anomalies as a function of  $D$  and BAZ to major lithosphere velocity anomalies or plate boundaries along the way of travel would be a very important result. For enabling such investigations primary station residual data should be preserved and not be manipulated by trying to reduce them by applying station corrections before reporting the data to national or international seismological data or network centers.

According to Abercrombie (1994) surface-wave focusing seems to be the main cause for the anomalously high  $M_s$  magnitudes of continental earthquakes relative to their seismic moments, rather than differences in the source process. Therefore, she suggests that in order to obtain reliable, unbiased estimates of regional seismic strain rate and hazard, local/regional moment-magnitude relationships should be preferred to global ones.

**Fig. 3.44a** Difference between  $M_s_{BB}(CLL)$ – $M_s(NEIC)$ , based on earthquakes recorded between September 1992 and December 2007. Black dots - individual measurements, bold red dots – average values over increments of  $1^\circ$  in distance together with their standard deviation (vertical red bars). Red line - moving average trend. On average CLL  $M_s_{BB}$  is 0.36 m.u. larger than  $M_s(NEIC)$ .

**Fig. 3.44b** Differences between station  $M_s_{BB}(CLL)$  and global  $M_s(NEIC)$  event averages for different source regions.

**Question 10: How do deviations from the standard instrument responses affect  $M_s$ \_BB and  $M_s$ \_20?**

There is no adverse effect on the measured values of  $V_{\max}$  for  $M_s$ \_BB if the passband range of the velocity-proportional BB response covers the range of periods within which  $V_{\max}$  for  $M_s$ \_BB should be measured, i.e., between about 3 s and 60 s. At least periods up to 40 s, which make for the vast majority of data, should be covered (see Fig. 3.40).

With respect to  $M_s$ \_20 we show in IS 3.3 that even large deviations in the LP response from the recommended WWSSN-LP standard may not bias  $M_s$ \_20 magnitudes as long as it is assured, that the passband range of the alternative response covers with its maximum magnification the period range of 18 to 22 s. This could be demonstrated by filtering the BB records so that they simulate SRO-LP records. The SRO-LP response differs very much from the WWSSN-LP response (see Fig. 3.20) and has the advantage of strongly reducing ocean microseisms with periods between about 3 to 8 s, thus improving the SNR and increasing the number of events for which  $M_s$ \_20 can be measured. None the less, the derived  $M_s$ \_20 values agree within 0.1 m.u. with standard  $M_s$ \_20 (see Figure 14 in IS 3.3) and thus can be reported as such and also their amplitude readings with the nomenclature IAMs\_20.

### 3.2.5.2 Body-wave magnitude scales and the new IASPEI standards

Gutenberg (1945b and c) developed a magnitude relationship for teleseismic body waves such as P, PP and S, measured on broadband or long-period instruments at periods of 2-20 s (Abe, 1981a and 1984; Abe and Kanamori, 1979 and 1980). It is based on theoretical amplitude calculations from a point source, corrected for geometric spreading and only distance-dependent attenuation and then adjusted to empirical observations from shallow and deep-focus earthquakes, mostly in intermediate-period records:

$$mB = \log (A/T)_{\max} + Q(\Delta, h). \quad (3.43)$$

Gutenberg and Richter (1956a) published a table with  $Q(\Delta)$  values for P-, PP- and S-wave observations in vertical ( $V=Z$ ) and horizontal ( $H$ ) components for shallow shocks (see Tab. 7 in DS 3.1), complemented by diagrams  $Q(\Delta, h)$  for PV, PPV and SH (Figures 1a-c in DS 3.1) which enable also compatible magnitude determinations for both shallow and intermediate to deep earthquakes (see Abe and Kanamori, 1979).

In order to use the Gutenberg and Richter (1956a)  $Q(\Delta, h)$  PV diagram in computer processing, the NEIC manually digitized the diagram, creating a table with increments of source depth (see Table 2 in IS 3.3) and a computer program for interpolation between these values (PD 3.1). Both are now used by the NEIC and the ISC as the common basis for calibrating P-wave magnitudes, thus eliminating earlier slight discrepancies in their magnitude calculations due to somewhat different scanning and interpolation. Therefore, these calibration values and the interpolation program should be used in future by other seismological agencies and observatories as well. The  $Q(\Delta, h)$  values are correct when amplitudes are given in micrometers ( $10^{-6}$  m).

Gutenberg and Richter (1956a) proposed to calculate mB values, originally termed *unified magnitude*  $m$ , for all three types of body waves. Because of their different nature and/or

propagation paths they also differ in their frequency content. In addition, these body waves phases leave the source at different take-off angles and/or have different radiation pattern coefficients. Using them jointly for the computation of event magnitudes significantly reduces the effect of the source mechanism on the magnitude estimate, especially, if only data from a few station with insufficient azimuthal coverage are available. Gutenberg and Richter (1956a) also scaled  $m = m_B$  to the earlier magnitude scales  $M_L$  and  $M_s$  so as to match them at magnitudes between about 6 to 7.

**Note:** Up to the present there is still widespread confusion within the seismological community what the **unified magnitude  $m$**  really meant and aimed at. Even in recent publications one finds wrong equating  $m = m_b$  (e.g., in Scordilis, 2006). Many seem not to have read or have had access to the relevant original publications nor understood up to now the principal difference between the short-period narrowband  $m_b$  and the medium-period broadband  $m_B$ . Thus there is an obvious need for a clarifying summary.

Originally, Gutenberg and Richter aimed at calculating a “unified magnitude”  $m$  by converting body-wave magnitude estimates into equivalent  $M_s$  values, which they had agreed upon as being a magnitude standard. This has been practiced, with the exception for intermediate and deep earthquakes, more or less, when calculating the  $M$  values in Gutenberg and Richter’s (1954) “Seismicity of the Earth”. However, in Gutenberg and Richter (1956b) they express already:

*“It is believed that magnitudes determined from body waves of teleseisms are more coherent with the original scale (meaning  $M_L$ , P.B.) than those from surface waves, which have been in use as the general standard. If further investigation confirms this, it will be established that the magnitudes above 7 determined from surface waves have been overestimated, while those below 7 are underestimated.... A complete revision of the magnitude scale... is in preparation. This will probably be based on  $A/T$  rather than amplitudes.”*

Gutenberg (1956) added:

*“In the present paper the “unified magnitude”  $m$  is used throughout for energy calculations. It is assumed to be connected with **the old magnitude  $M_s$**  by*

$m = 0.63M_s + 2.5$  (1) *and with **the newly determined values of  $M_B$**  ... by  **$m = M_B$** . (2).*

*The energy  $E$  of earthquakes is calculated from  $\log E = 5.8$  (in erg; P.B.) +  $2.4m$ . (3)*

*It should be emphasized that equations (1), (2) and (3) are tentative and should be revised if more data become available.”* (This we have done with Eqs. (3.98-3.100) for (1) and Eq. (3.137) for (3) for  $M_B = m_B = m_{B\_BB}$ )

Finally, when publishing the revised body-wave magnitude calibration tables and charts, Gutenberg and Richter (1956) write consistently  $m_B$  instead of  $M_B$  and summarize:

*“Pending further research it is recommended that  $M_L$  continue to be used as heretofore, but  $M_s$  (and ultimately  $M_L$ ) should be referred to  **$m_B$  as a general standard, called the unified magnitude** and denoted by  $m$ . Tentatively.”*

Later, with the introduction on a global scale of the WWSSN short-period 1s-seismometers (for response see Fig. 3.20), it became common practice at the NEIC to use the calibration function  $Q(\Delta, h)$ , developed for medium-period amplitude readings on relatively broadband recording, for band-limited short-period PV measurements only. According to Fig. 3.45, this results in the case of strong earthquakes and when compared with their  $M_{s\_20}$  or  $m_B$  estimates, in an about 1 m.u. lower  $m_b$  value (termed *spectral component of saturation*). In addition, it was recommended in the early 1960s that the largest amplitude be taken within the first few cycles (Engdahl and Gunst, 1966; Willmore, 1979) instead of measuring the maximum amplitude in the whole P-wave train. To measure the largest amplitude within the first 5.5 s after the P onset is still the standard practice at the IDC of the CTBTO (see Chapter 15). Since the average rupture duration of earthquakes of magnitude 6, according to relationship (3.3), is about 6 s, such a fixed measurement time-window will add for larger earthquakes additionally a *time-window component of saturation* (see Fig. 3.46).

**Fig. 3.45** Illustration of estimating approximately the average amount of spectral magnitude saturation of mb with respect to Ms<sub>20</sub> or mB\_BB on the basis of the scaling law in Fig. 3.5.

**Fig. 3.46** Short-period WWSSN and broadband (BB) records of a strong Mw8.4 Peru earthquake. They illustrate the measurement of mb and mB at the largest amplitudes in the P-wave train near 90 s after the P-wave onset. The difference in velocity amplitude of 123 μm/s in the BB record and 8 μm/s in the time-differentiated WWSSN-SP record is due to spectral saturation according to Fig. 3.31, explaining the difference mb-mB = - 1.2. If one would measure for mb  $A_{\max}$  within the first 5.5 s, then this difference would increase by -0.5 m.u. (time-window component of saturation). (Copy of Figure 1 in Bormann and Saul, 2008, Seism. Res. Lett. 79, No. 5, p. 699; © Seismological Society of America).

One should be aware that the practice of measuring the P-wave amplitude so early in so short a window was due to the focused interest in the 1960s on discriminating between earthquakes and underground nuclear explosions (UNE). For the latter, having source durations in the order of milliseconds only, their maximum P-wave amplitudes are always observed within the first few seconds after the P onset. Therefore, such a short time-window even improved the discrimination between earthquakes and UNE based on the  $M_s$ - $m_b$  criterion (see section 11.2.5.2??? of Chapter 11).

Yet, Bormann and Khalturin (1975) argued against it in the more general interests of earthquake seismology and recommended (quote):

*“We are of the opinion that the extension of the time interval for the measurement of  $(A/T)_{\max}$  up to 15 or 25 sec., as proposed ...in the Report of the first meeting of the IASPEI Commission on Practice (1972) ...is not sufficient in all practical cases, especially not for the strongest earthquakes with  $M > 7.5$ ....To reduce the systematic differences between magnitude determinations from body waves and surface waves, short-period or medium-period broad-band records should be preferred to short-period narrow-band ones for the MB-determination and the time interval for measuring the maximum value of  $A/T$  should be extended to about 1 minute for the strongest earthquakes.”*

In response, the IASPEI Commission on Practice revised its earlier 1972 measurement recommendation in 1978, stating that the maximum P-wave amplitude for earthquakes of small to medium size should be measured within 20 s from the time of the first onset and for very large earthquakes up to 60 s (see also Willmore, 1979, p. 85). This somewhat reduced the discrepancy between  $mB$  and  $m_b$  but in any event both are differently scaled to  $M_s$  and  $M_w$  with the short-period  $m_b$  necessarily saturating earlier than medium-period  $mB$  (see Fig. 3.47).

**Fig. 3.47** Approximate relationships and ranges of variability between  $M_l$ ,  $m_b$ ,  $mB$  and  $M_s$  with respect to non-saturating  $M_w$  (redrawn and modified from Fig. 4, p. 193, in Kanamori 1983; based on the kind permission of Elsevier Science Publishers for reprinting in NMSOP 2002).

However, some of the national and international agencies have only much later or not even as of now changed their practice of measuring  $(A/T)_{\max}$  for mb in a very limited time-window. E.g., the International Data Centre for the monitoring of the CTBTO still uses a time window of only 6 s (5.5s after the P onset), regardless of the event size. In contrast, the former Soviet/Russian practice (but also the East German practice, see Tab. 3.1 and Fig. 3.69 in section 3.2.5.2) of analyzing short-period records was always to measure the true P-wave maximum on the entire record. These magnitudes, reaching values between 7.3 to 7.6 for the strongest earthquakes, were denoted as MPV(A) or mSKM, because of using modified, relatively broadband short-period Kirnos type of instruments with a response as in Figure 1 of IS 3.7). Similar “whole P-wave train” mb magnitudes were later determined also by Koyama and Zeng (1985), denoted  $m_b^*$ , and by Houston and Kanamori (1986), denoted  $\hat{m}_b$ , which also reached values up to 7.6. With respect to saturation, mSKM,  $m_b^*$  and  $\hat{m}_b$  behave much like MI, as could be expected from their common frequency band used and considering that MI is determined also from the maximum amplitude in the whole short-period event record. MI saturates around 7.5 as well (see Fig. 3.47).

Taking into account the above facts, the CoSOI WG on Magnitudes recommends two P-wave **IASPEI standard magnitudes, mb and mB\_BB**, with suitably modified measurement procedures (IASPEI 2005, 2011 and 2012). In short they are defined as follows:

$$mb = \log_{10}(A/T) + Q(\Delta, h) - 3.0, \quad (3.44)$$

where  $A$  = P-wave ground amplitude in **nm** calculated from the maximum trace-amplitude in the **entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, and ending preferably before PP);  $T$  = period in seconds,  $T < 3$  s; of the maximum P-wave trace amplitude.

$Q(\Delta, h)$  = attenuation function for **PZ** (P-waves recorded on vertical component seismographs) established by **Gutenberg and Richter (1956a)** in the tabulated or algorithmic form as used by the U.S. Geological Survey/National Earthquake Information Center (USGS/NEIC) (see Table 2 in IS 3.3 and PD 3.1);  $\Delta$  = **epicentral distance in degrees,  $20^\circ \leq \Delta \leq 100^\circ$** ;  $h$  = **focal depth in km**;

and where both  $T$  and the maximum trace amplitude are measured on output from a **vertical-component** instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a **WWSSN short-period** seismograph (see Figure 1 and Table 1 in IS 3.3) with  $A$  being determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-SP response at period  $T$ .

Note that Fig. 3.7 in section 3.1.2.4 shows how new standard mb data relate to mb measured within the first 6 s after the P onset.

The standard relationship for mB\_BB reads as follows:

$$mB\_BB = \log_{10}(V_{\max}/2\pi) + Q(\Delta, h) - 3.0, \quad (3.45)$$

where  $V_{\max}$  = ground **velocity in nm/s** associated with the maximum trace-amplitude in the **entire P-phase train** (...as for mb...), as recorded on a vertical-component seismogram that is **proportional to velocity**, where the period of the measured phase,  $T$ , should satisfy the

condition  $0.2 \text{ s} < T < 30 \text{ s}$ , and where  $T$  should be preserved together with  $V_{\max}$  in bulletin data-bases; and  $Q(\Delta, h)$ ,  $\Delta$  and  $h$  as for mb. Equation (3.45) differs from the equation for  $m_B$  of Gutenberg and Richter (1956a) by virtue of the  $\log_{10}(V_{\max}/2\pi)$  term, which replaces the classical  $\log_{10}(A/T)_{\max}$  term.

Formula (3.43) can be simplified by including  $-\log_{10}(2\pi) = -0.8$  into the constant, then reading

$$mB\_BB = \log_{10}V_{\max} + Q(\Delta, h) - 3.8. \quad (3.45a)$$

For more details and comments on mb and mB\_BB see IS 3.3.

### Question 1: Is modern mB\_B compatible with the classical Gutenberg mB?

Gutenberg measured himself or used measurements of P-wave amplitudes and periods published in other station bulletins that were commonly based in these years on relatively broadband medium-period instruments with responses that resemble that of the classical Russian Kirnos instruments of type SK and SKD (see the relative response curves 6 and 7 in Figure 1 of IS 3.7; for SKD also the Kirnos response in Fig. 3.20). Most of these response curves were more or less displacement proportional in the period range between  $0.1 \text{ s} < T < 10\text{--}2 \text{ s}$ , such as Mainka, Wiechert, Galitzin or Bosch-Omori (Kanamori, 1988, or Figure 5.6 in Lay and Wallace, 1995). Periods of  $A_{\max}$  measured in displacement records (and thus relating to  $(A_{\max}/T)$ ) tend to be somewhat larger than periods of  $V_{\max}$  in velocity records which correspond to  $(A/T)_{\max}$ . Although Gutenberg aimed at the latter, common practice has been to measure  $(A_{\max}/T)$  instead. This is obvious from Fig. 3.48 too, which compares traditional and period-wise more noisy measurements of P-wave  $A_{\max}$  for classical mB at the CENC with related measurements of  $T$  at  $V_{\max}$  for mB\_BB. Notable in both figures is the exponential increase of  $T$  for  $mB > 6$ . On average this is related to the exponential increase of the corner period of seismic source spectra with magnitude. The great scatter of measured periods at individual stations is both due to the stress drop-dependence of the corner period (see Fig. 3.15) and local station site effects. In records of weaker earthquakes with low SNR, however, the measured values of  $T$  may already be biased by the prevailing periods of ocean storm microseisms with periods between about 3 to 8 s.

**Fig. 3.48** Dependence on mB\_BB (left-hand panel) and on mB\_CENC (right-hand panel) of the P-wave periods observed at individual stations when measuring  $V_{\max}$  on broadband-velocity records or  $A_{\max}$  on broadband displacement records of SK (Kirnos) type. The polygon line connects the average periods measured at the considered magnitude, the curved line is the exponential fit to it. (Copy of Figure 6 in Bormann et al. (2009), Bull. Seism. Soc. Am. 99, 3, p. 1873; © Seismological Society of America).

A consequence of this procedural difference of measuring directly  $V_{\max}$  (as for  $M_{s\_BB}$  too) may be the not perfect 1:1 trend of the regression relations between  $mB(BB)$  and  $mB(CEN)$  (see Fig. 3.49). For magnitudes  $< 6.5$   $mB(BB)$  yields somewhat larger values than  $mB$ . However, in the range  $mB > 6$ , in which Gutenberg measured this magnitude only, the average difference is  $\leq 0.1$  m.u. and the overall correlation coefficient is very high. Therefore, we can conclude that modern  $mB(BB) = mB\_BB$  is compatible with the  $mB$  intended and practised by Gutenberg within the acceptable error limit of 0.1 m.u. for the standard.

### ***Question 2: How relates standard mb to mb(NEIC)?***

Short-period narrow-band  $mb$  is not a body-wave magnitude recommended by Gutenberg. It has unilaterally been introduced by the concerned U.S. agencies in conjunction with the deployment of the World Wide Standard Seismograph Network (WWSSN) and short-period seismic arrays in the 1960s and 1970s. Since then  $mb$  has become an indispensable de facto standard magnitude, and the vast majority of global magnitude data is now  $mb$ . The reason is that short-period narrowband high-gain records enable magnitudes to be assigned to events that are more than an order of magnitude smaller than can be assigned with  $mB$  which is measured on much more noisy broadband records. However, since its inception, the measurement procedures for  $mb$  have changed several times.

Early U.S.  $mb$  values were measured within the first few P-wave cycles in short-period records. They saturated already near to 6 (see Fig. 3.7). However, following the IASPEI resolution of 1978, the USGS/NEIC changed practice later on and measured  $A_{\max}$  routinely either in the first 20 s or, after automation of the analysis procedure, within the first 10 cycles. Yet, analysts were instructed to extend this window in the final review for the PDE up to 60 s in the case of strong earthquakes. Moreover, the early WWSSN-SP records were later substituted by filtering with the PDE response, which has a steeper roll-off for  $f > 1$  Hz, a slightly larger relative bandwidth and period of maximum gain (see Figure 3 in IS 3.3). Nevertheless, one can expect standard  $mb$  to be close to post-1978  $mb(NEIC)$ , at least for the vast majority of data. According to Fig. 3.50 this is true for  $mb$  between about 4 and 6.5, for larger magnitudes, however, again  $mb(NEIC)$  tends to be somewhat smaller, saturating around 7 instead of around 7.5 as standard  $mb$ . Also, when comparing these two data sets, the data scatter is significantly larger and the correlation coefficient much smaller than in the comparison of standard  $M_{s\_20}$  with  $M_s(NEIC)$  (Fig. 3.37).

**Fig. 3.49** Regression relationships (standard and orthogonal) between  $mB(BB)$  and classical  $mB(CENC)$ .  $RXY$  = correlation coefficient,  $RMSO$  = orthogonal root mean square error. Figure based on data published in Bormann et al. (2009).

**Fig. 3.50** Regression relationships (standard and orthogonal) between standard  $mb$ , measured at the China Earthquake Network Center (CENC), and  $mb(NEIC)$  for the same events. Legend as in Fig. 3.49. Figure based on data published in Bormann et al. (2009).

**Question 3: How relate standard mb and mB\_BB to each other?**

Fig. 3.51 compares event standard magnitudes mb and mB\_BB, as measured at (CENC) on records of the China National Seismograph Network, and Fig. 3.52 the same but based on records of the German Regional Seismic Network (GRSN), analyzed by S. Wendt.

**Fig. 3.51** Regression relationships (standard and orthogonal) between standard mb and mB(BB), measured at CENC. Legend as in Fig. 3.49. Figure based on data published in Bormann et al. (2009).

**Fig. 3.52** Data and regression relationships (standard and **orthogonal = thick black line**) between the event standard mb and mB\_BB as determined with records of the German Regional Seismic Network (GRSN). The medium and light grey shaded bands limit the 1σ and 2σ standard deviation (SD) range of the OR relationship.

Both Fig. 3.51 and 3.52 show the same tendency, namely, that

- $mB\_BB$  is always larger than  $mb$  and differs the more the stronger the earthquake;
- the difference is smallest (around +0.1 m.u.) at magnitude 5, grows on average to about +0.5 m.u. around  $mB(BB) = 8$ , and may reach in individual cases about one m.u. (see also Fig. 3.31).

Moreover, the average SD values for the calculated event  $mb$  and  $mB$ , given in the lower right corner of Fig. 3.52, indicate that on average the measurement errors for  $mB$  (0.15 m.u.) are significantly smaller than for  $mb$  (0.21 m.u.), less smaller at shorter periods but much smaller for stronger earthquakes with  $V_{max}$  recorded at longer periods.

**Question 4: How does the large scatter of period readings in BB records affect the estimate of  $mB\_BB$ ?**

Fig. 3.48 revealed the large scatter of periods at which  $V_{max}$  is measured in all magnitude ranges. Yet, Fig. 3.53 shows a systematic trend, namely, that the difference  $mB\_BB-mb$  grows on average with the measured period which is related to the corner frequency of the seismic source spectrum and thus to earthquake magnitude itself. The difference between these two magnitudes is less than +0.3 m.u. when the  $mB$  periods fall into the range at which also  $mb$  is measured. The then still positive  $mB$  residuals are likely due to the larger relative bandwidth of the BB records as compared to WWSSN-SP records (see Chapter 4). Yet, the difference between  $mB\_BB$  and  $mb$  may reach 1 m.u. for great earthquakes measured at period around 15 to 25 s, which is in agreement with Fig. 3.45.

**Fig. 3.53** Relationship between the difference of  $mB(BB)-mb$  on the period at which the  $V_{max}$  for  $mB(BB)$  calculation was measured. The data have been measured on velocity-proportional records of the broadband German Regional Seismic Network (GRSN).

The large data scatter in Fig. 3.53 at comparable magnitude differences is most likely due to both stress-drop and thus corner-frequency differences of earthquakes with comparable moment release as well as to local station site effects. This, however, does not essentially bias

the stability and representativeness of the  $V_{\max}$  readings for reliable  $mB\_BB$  estimates, as the following case, observed on teleseismic station records of the GRSN, illustrates (according to Bormann et al., 2009):

- Earthquake off the east coast of Honshu, 18 January 2006, average network distance  $\Delta \approx 82^\circ$ , 16-station network  $mB\_BB = 6.06 \pm 0.23$  with an average  $T = 2.4 \pm 1.4$  s; station IBBN  $mB\_BB = 6.10$  at  $T = 0.7$  s and station BUG  $mB\_BB = 6.10$  at  $T = 5.0$  s; i.e., equal  $mB\_BB$  although  $T_{BUG} \approx 7 \times T_{IBBN}$ .

Thus we can conclude, that the variability of period measurements in BB records on often not very harmonic oscillations does not essentially bias the readings of  $V_{\max}$ . Generally, measurement errors of  $mB$  are significantly smaller than for short-period  $mb$  (compare also Figs. 3.23 and 3.24).

#### ***Question 5: How do deviations from the standard responses affect $mb$ and $mB\_BB$ ?***

$V_{\max}$  and  $T$  readings for  $mB\_BB$  will not be biased if the velocity-proportional passband range of the broadband records covers fully the range of periods within which  $mB\_BB$  is supposed to be measured, i.e., between 0.2 s to 30 s. In fact, however, periods below 1 s are rarely observed, usually for deep earthquakes only.

$mb$  measurements on narrowband short-period records are more strongly affected by the effective relative bandwidth, the steepness of gain roll-off beyond the corner periods of the passband and by the exact period at which the response reaches its maximum gain. Therefore, it is advisable to adhere to the WWSSN-SP simulation filter parameters prescribed for standard  $mb$ . Yet slight differences in the high-frequency roll-off, as they had originally been implemented in some analysis software, may be acceptable within the 0.1 m.u. tolerance range for standard magnitudes (see Fig. 11 and discussion in IS 3.3). For earthquakes with magnitudes  $M_w < 4$  and thus average  $f_c > 2$ -3 Hz of their source spectra (see Fig. 3.5) it would be acceptable to shift the record response to higher frequencies and steepen its slope to lower  $f$  so as to increase the SNR, provided that the spectral displacement plateau and/or velocity peak is still sampled. This would assure good scaling of the  $mb$  for small events to  $M_w$  and/or  $M_e$ . See also related discussions in sections 5.1.1 and 5.1.2 of IS 3.3).

#### ***Question 6: To what extent are differences between $mb$ and $mB\_BB$ due to frequency-dependent attenuation?***

Up to now, both  $mb$  and  $mB$  are calibrated with the Gutenberg and Richter (1956a)  $Q(\Delta, h)_{PZ}$  functions although the latter had been derived from readings with periods between about 2 and 20 s (Abe and Kanamori, 1979) and were intended to be used for calibrating mainly intermediate-period amplitude readings within this range. This raises the question whether it is acceptable at all to use these calibration functions for 1 s P-wave  $mb$  as well or whether the observed systematic differences between  $mb$  and  $mB$  are – at least partially – due to the neglectance of frequency-dependent attenuation. One should note, however, that Gutenberg and Richter obviously did not believe in the applicability of the frequency-dependent attenuation model for their problem of magnitude determination. Because by measuring  $A/T$  instead of  $A$  they compensated in fact largely for the exponential frequency-proportional increase of displacement amplitude attenuation by multiplying  $A$  with  $f = 1/T$ . Thus they

derived a linear model of attenuation proportional to  $\exp(-0.00006 L)$ , where  $L$  is the total length of the ray path from the station to the source. This explains the stability of the G&R  $Q(\Delta, h)$  functions, making them theoretically even equally applicable to 10 s data and 10 Hz data. Although this may not fully be true for frequencies above about 0.5 Hz, various studies have shown (see section 2.5.4.2 on *wave attenuation* in Chapter 2) that there is no clear empirical evidence for frequency-dependent  $Q$  for periods above 2 – 4 s and that for higher frequencies the expected exponential increase in displacement amplitude attenuation is strongly reduced by absorption-band effects. Moreover, it is a matter of fact that the observed differences between  $m_b$  and  $m_B$  depend chiefly on magnitude itself and that they can almost perfectly be explained by the magnitude-dependent shift of the corner frequency of the source spectrum towards lower frequency and the average decay of the velocity amplitudes for  $f > f_c$  with the first order (see Fig. 3.45).

With the same reasoning, the IASPEI standard calibration function for  $M_s$ , measuring  $A/T$  or nowadays directly velocity amplitudes for  $M_s\_BB$  in a wide range of periods is rather stable and reliable as well without accounting for frequency-dependent attenuation. When, however, measuring surface-wave displacement amplitudes in narrow bandpass ranges for  $M_s$  determination, as done in the Bonner et al. (2006)  $M_s(VMAX)$  procedure, then it is indeed indispensable to correct such amplitudes for frequency-dependent attenuation to make them on average compatible with  $M_s\_BB$  or the so-called Prague- $M_s$ . That this is indeed the case has been demonstrated by both Bonner et al. (2006) and Bormann et al. (2009).

Regrettably, reliable experimental data on frequency-dependent attenuation are still rare and model calculations may yield rather different results depending on whether one uses attenuation models with the **quality factor  $Q$**  depending on frequency for shorter periods or not. Therefore, until more reliable empirical spectral attenuation data for ground-motion velocities measurements become available, it is still justified to use the Gutenberg-Richter calibration functions for both  $m_b$  and  $m_B\_BB$  determinations.

### **Question 7: How reliable are the Gutenberg-Richter $Q(\Delta, h)_{PV}$ curves/tables?**

The Gutenberg and Richter (1956a) calibration curves  $Q(\Delta, h)_{PV}$  show many details (see Fig. 1a in DS 3.1), probably too many in view of the interpolation through rather noisy data measured with instruments of different response, often not well known gain and station site effects (see Veith, 1998) and less accurate estimates of epicentral distance and depth they had available in their days. Already efforts by Christoskov et al. (e.g., 1978, 1985 and 1991) for the development of a homogeneous magnitude system (HMS) based on carefully selected first-order stations over Eurasia and accounting for station site corrections showed that the average P-wave calibration curve for both short-period and medium-period amplitude readings from shallow events in the epicentral distance range between 20° and 100° is much smoother than the respective Gutenberg-Richter  $Q(\Delta)$ . The same holds for the distance-depth corrections derived by Veith and Clawson (1972), Lilwall (1987) and Rezapour (2003) for short-period P-waves. For shallow sources the differences between the  $P(\Delta)$  of Veith and Clawson (1972) and  $Q(\Delta)$  reach up to 0.3 m.u. in some limited distance ranges between 20° and 100°. Saul and Bormann (2007) came to the same preliminary result for new broadband  $m_B\_BB$  calibration functions. The latter authors additionally showed that the differences in the regional range between 5° and 20° epicentral distance may be even larger, up to about 0.8 m.u. around 10° (see Figure 16 in IS 3.3). These differences, especially in the regional distance range, may however differ from region to region. Further investigations are required

to clarify this. Standardized mB measurements will ease this task. With respect to the reliability of the medium-period  $Q(\Delta, h)_{PV}$  curves for deep earthquakes see also section 3.2.6.1 and with respect to the alternative Veith and Clawson  $P(\Delta, h)$  curves for 1 Hz P waves section 3.2.6.2. Both Nolet et al. (1998a) for their broadband mb and Rezapour (2003) for his short-period mb distance-depth correction terms use the values of scalar seismic moment  $M_0$  in the Harvard Centroid Moment Tensor catalog to calibrate the P-wave amplitudes.

### ***Still open problems:***

Despite the strong recommendation of the Committee on Magnitudes at the IASPEI General Assembly in Zürich (1967) to report the magnitude for all waves for which calibration functions are available, the ISC and NEIC determine no body-wave magnitudes from PP or S waves despite their merits discussed above and the fact that digital broadband records now allow easier identification and parameter determination of these later phases.

1) At distances beyond  $100^\circ$  the P-wave core shadow prevents to measure mb and mB. Yet, good PP readings from strong earthquakes are possible and calibration functions  $Q(\Delta, h)$  available for PPH and PPV up to  $170^\circ$ . According to Bormann and Khalturin (1975), mB determined from P and PP waves scale perfectly. The orthogonal regression is

$$mB(PP) = mB(P) + 0.05 \pm 0.15 \text{ m.u.} \quad (3.46)$$

If, however, short-period amplitude readings for P and PP are used instead, the orthogonal relationship is magnitude-dependent ( $mb(PP) = 1.25 mb(P) - 1.22$ ) and the standard deviation is much larger ( $\pm 0.26$  m.u.). This again testifies the greater stability of body-wave magnitudes based on medium- to long-period readings.

2) The suitability of large amplitude readings of PKP in the distance range of the core caustic around  $145^\circ$  and beyond for magnitude determinations has also been ignored so far (see 3.2.6.3 and EX 11.3).

3) No proper discrimination had been made in the past at the international data centers between data readings from different kinds of instruments or filters, although respective recommendations were made already at the joint IASPEI/IAVCEI General Assembly in Durham, 1977. However, with the step-wise introduction of the new IASPEI standards since 2010 for some of the most widely used magnitudes both the measurement parameters as well as the related unique nomenclature for measured amplitudes and magnitudes have now been fixed (see Table 4 in IS 3.3). On the other hand, this necessitates that magnitude data resulting from non-standard procedures, which can – on average - not reproduce for the same type of magnitude the standard results within 0.1 m.u., be reported with a specified nomenclature. First proposals have been made in IS 3.2 and are expected to be refined in future.

## **3.2.6 Other amplitude, period, intensity or tsunami based magnitude scales (P. Bormann)**

Below we describe several other complementary procedures for magnitude estimation. They are not (yet) based on IASPEI recommended standards but are (or may become) also useful for applications in seismological practice.

### 3.2.6.1 Broadband and spectral P-wave magnitude scales

#### *Broadband P-wave magnitude scale for intermediate and deep earthquakes*

A calibration function  $Q_b(\Delta, h)^{NKC}$  has been derived by Nolet et al. (1998a). It is based on  $V_{\max}$  measurement on broadband velocity recordings of P waves (bandpass between 0.01 and 2 Hz) and applicable to intermediate and deep earthquakes in the ranges  $20^\circ \leq \Delta \leq 90^\circ$  and  $100 \text{ km} \leq h < 700 \text{ km}$ . For deriving this calibration function, the measured amplitudes have been normalized to a scalar seismic moment  $M_0 = 10^{18} \text{ Nm}$ , which corresponds to a **short-period**  $mb = 5.7$  according to a relationship  $mb = (\log M_0 - 4.3)/2.4$  for deep earthquakes published by Giardini (1988) and to  $Mw = 5.9$  according to the IASPEI standard  $Mw$ - $M_0$  relationship  $Mw = \log(M_0 - 9.1)/1.5$ .

The  $Q_b(\Delta, h)^{NKC}$  plot looks much smoother (Fig. 3.54) than the Gutenberg and Richter (1956a) plot of  $Q(\Delta, h)_{PZ}$  (see Figure 1a in DS 3.1). Even some of the larger details in the Gutenberg-Richter plot are missing, yet the isolines follow the main feature of  $Q(\Delta, h)_{PZ}$  (around 300 to 400 km depth) and the trend with distance, have small standard deviations and no bias with depth with respect to  $\log M_0$  when normalized to 0 for shallow events (Nolet et al., 1998b).

Quantitatively, the values of  $Q_b(\Delta, h)^{NKC}$  are generally lower than those of  $Q(\Delta, h)_{PZ}$  because Nolet et al. (1998a) wrote their  $mb$  formula in the way as we wrote also (3.37a) for  $Ms\_BB$  and (3.45a) for  $mB\_BB$ , i.e., by including  $-\log 2\pi = -0.8$  into the constant. But it remains an average difference of about -0.3 m.u. with quite some scatter. The scatter may be due to the many local details in the G-R plot that could - partially at least - be related to uncorrected station site effects (Veith, 1998) (see discussion in section 3.2.5.2 related to Question 7). The negative average residual with respect to  $Q(\Delta, h)_{PZ}$ , however, is obviously due the scaling of  $mb(\text{Nolet})$  to  $mb = 5.7$  (or  $Mw = 5.9$  for  $M_0 = 10^{18} \text{ Nm}$ ), which on average corresponds according to Bormann et al. (2009) to an  $mB\_BB = 6.0$  (see also Fig. 3.53 and the average difference of  $mB$ - $mb$  of about 0.3 m.u. for periods of P around 3 s in broadband records. According to Nolet et al. (1998a) the dominant periods of the maximum velocity pulses of deep earthquakes in broadband records fall in the range between 1 – 4 s but are occasionally even larger. Thus they are longer than the dominant periods around 1 s of the short-period P waveforms on which the amplitudes for  $mb$  are commonly read. Therefore, in order to make on average the numbers given on the isolines of Fig. 3.54 comparable with the Gutenberg-Richter (1956a)  $Q$ -values, which were derived for scaling medium-period  $mB$  measurements, one would need to correct for the downscaling to short-period  $mb$ .

No results of a systematic comparison of  $mb(\text{Nolet})$  with standard  $mB\_BB$  for identical  $V_{\max}$  readings have become known to us so far. This, however, would be necessary and the reasons for differences better be understood before one can judge on the potential advantage (or not) of replacing for earthquakes deeper than 100 km the Gutenberg-Richter  $Q(\Delta, h)_{PZ}$  by  $Q_b(\Delta, h)^{NKC}$ . Only after a rigorous comparison of  $mb$  and  $mB\_BB$  values calculated for deep earthquakes by using both the Gutenberg-Richter and the Nolet et al.  $Q$ -values and their confrontation with independent accurate and stable magnitude measurements such as  $Mw$  one might be able to decide which calibration data are better suited for calculating the two standard body-wave magnitudes  $mb$  and  $mB\_BB$  for deep earthquakes. Such an investigation should be encouraged.

**Fig. 3.54**  $Q_b(\Delta, h)^{NKC}$  calibration values, averaged over  $20^\circ$  and 200 km depth range. Copy of Fig. 3 in Nolet et al. (1998), *Geophys. Res. Lett.*, **25**, 9, p. 1453; © American Geophysical Society.

### *Spectral P-wave magnitudes*

Duda and Kaiser (1989) recommended the determination of spectral magnitudes based on measurements of largest amplitudes in one-octave filtered digital broadband records of P waves. Fig. 3.55 show such bandpass records of two earthquakes with comparable magnitude  $m_b$ , recorded at comparable distance, but having different source depth and mechanism. Accordingly, the amplitudes in different spectral ranges differ a lot. This is due to regional differences in ambient stress conditions and related stress drop.

Duda and Yanovskaya (1993) calculated theoretical spectral amplitude-distance curves based on the IASP91 velocity model (Kennett and Engdahl, 1991) using two different attenuation models aiming at magnitude calibration of spectral amplitude measurements (see Fig. 2.39 in Chapter 2). This effort is a response to the “saturation” problems discussed above. Combining the spectral magnitude estimates yields smoothed average values of the radiated seismic spectrum, its spectral plateau, corner frequency and high-frequency decay and thus of  $M_0$  and stress drop of the given event. Thus one may draw inferences on systematic differences in the prevailing source processes (e.g., low, normal or high stress drop), related ambient stress conditions in different source regions but also on the amount and relative share of radiated high and low frequencies and thus of the potential of the earthquake to cause either strong shaking damage or generate a tsunami.

This, however, has so far not yet been the main concern of common seismological routine practice, which aimed at providing just a simple one (or two) parameter size-scaling of seismic events for general earthquake statistics and hazard assessment. Rather, spectral magnitudes were more considered a research issue, which could be tackled even more directly by calculating both  $M_0$  and the radiated seismic energy  $E_s$  proper, by estimating the corner frequency and shape of the overall source spectra from the corrected broadband record spectra and by determining and interpreting jointly both energy magnitude  $M_e$  and moment magnitude  $M_w$  and their difference (see IS 3.5). Good  $M_w$  and  $M_e$  estimates can nowadays already be done fully automatic within about 10-20 min after origin time and allow essentially the same inferences to be drawn as from the multi-bandpass filtering of broadband records (see, e.g., Choy and Kirby, 2004; Di Giacomo et al., 2010a; Bormann and Di Giacomo, 2011).

Therefore, this educationally very appealing concept of spectral magnitudes has not yet found broad application in observatory practice. A fine example is presented in Fig. 3.55.

**Fig. 3.55** Examples of broadband digital records proportional to ground velocity of the P-wave group from two earthquakes with  $m_b = 6.3$  and  $h = 49$  km (left), and  $m_b = 6.8$  and  $h = 97$  km (right), respectively. The earthquakes occurred in different source regions (Mexico and Kuriles). Below their BB records (uppermost traces) their one-octave bandpass-filtered outputs are plotted. The numbers 1 to 9 on the filtered traces relate to the different center periods between 0.25 s (1) and 64 s (9) in one-octave distance. Note that the somewhat “weaker” event on the left has its maximum recorded ground velocity in trace 7, corresponding to a center period of 16 s. In contrast, the  $m_b$ -wise stronger event on the right, for which one would on average expect an even longer corner period, has its  $V_{\max}$  at 1 s (trace 3). Thus, the 1-Hz spectral magnitude in the case of the Kurile earthquake would be much larger than for the Mexico earthquake, hinting to strong felt shaking and potential damage of exposed objects, not, however in the case of the Mexico earthquake with a very small amount of 1-Hz energy released. (Copied from Duda, 1986; with permission of Schweizerbart [www.schweizerbart.de](http://www.schweizerbart.de)).

### 3.2.6.2 1-Hz P-wave magnitude $m(P)$ and $m_b(IDC)$

Veith and Clawson (1972) developed a calibration function, termed  $P(\Delta, h)_{SP}$  (see Fig. 3.56), using short-period WWSSN vertical-component P-wave records of underground nuclear explosions, thus avoiding data scatter due to uncorrected source radiation pattern effects. The  $P(\Delta, h)_{SP}$  plot looks much smoother than the  $Q(\Delta, h)_{PZ}$  curves published by Gutenberg and Richter (1956a) and resemble, also at depth, much more an inverse  $A-\Delta$  relationship for short-period P waves as depicted in Figs 2.39 or 3.34. However, using only very shallow-depth sources, the calibration curves at depth are empirically not well constrained. They have been model-derived using still debatable attenuation models and therefore differ often significantly from both the Gutenberg and Richter (1956a) and the Nolet et al. (1998a) calibration curves

for vertical component P waves (compare with Figure 1a in DS 3.1 and Fig. 3.54 above, respectively). Yet, for shallow events mb(P) values agree well with mb(Q) (according to Veith, 2001, with an average difference of -0.03 m.u.) but have less scatter. Therefore, no wonder that the International Data Center (IDC) of the Comprehensive Test-Ban Treaty Organization (CTBTO) uses  $P(\Delta, h)_{SP}$  as standard calibration curve for calculating its mb(IDC) values (see Chapter 15).

For deeper events, however, mb(P) is systematically lower than mb(Q) (up to about 0.4 magnitude units at 450 to 640 km depth) due to a different attenuation law assumed in the upper mantle and transition zone (Veith, 2001). For more details on pros and cons see Nolet et al. (1998b) and Veith (1998). Also note, that deviating from the use of the Gutenberg-Richter  $Q(\Delta, h)_{PZ}$  functions, the calibration values given in Fig. 3.56 have to be applied to maximum P-wave peak-to-trough (2A) displacement amplitudes in units of  $\text{nm} = 10^{-9} \text{ m}$  (instead of peak-to-trough/2 amplitudes in  $\mu\text{m} = 10^{-6} \text{ m}$ ). Accordingly, the Veith and Clawson formula reads:

$$\text{mb(P)} = \log (A_{\text{max;peak-to-trough}}/T) + P(\Delta, h) \quad (3.47)$$

**Fig. 3.56** Calibration functions  $P(\Delta, h)$  for mb determination from narrow-band vertical-component short-period records with peak displacement magnification near 1 Hz (WWSSN-SP characteristic). (Modified according to Veith and Clawson (1972), Magnitude from short-period P-wave data, BSSA, **62**, 2, p. 446, © Seismological Society of America).

The Veith-Clawson magnitude calibration functions are officially used by the IDC in Vienna for mb determination although the IDC filter applied to the digital velocity-proportional broadband data prior to the amplitude measurements for mb results in a displacement response peaked around 3.4 Hz (Granville et al., 2005) instead of around 1 Hz, as required for the use of  $P(\Delta, h)$  (Veith, 2001). According to the spectral  $\log A$ -D curves calculated by Duda and Yanovskaya (1993) for the modified PREM attenuation model (see Fig. 2.39 in Chapter 2),  $\log A$  is in the distance range between  $10^\circ$  and  $100^\circ$  at 4 Hz about 0.15 to 0.5 units smaller

than at 1 Hz. Thus, the use of  $P(\Delta, h)$  in conjunction with the IDC filter response is physically not correct and tends to systematically underestimate  $m_b$ . This is further aggravated by the fact that the IDC determines  $A_{\max}$  within a time window of only 5.5 s after the P onset (Granville et al., 2005). This heuristic procedure, although very suitable for a best possible discrimination between earthquakes and underground explosions on the basis of the  $m_b$ - $M_s$  criterion (see 11.2.5.2??), is not appropriate for proper earthquake scaling, at least for events with magnitudes larger than 6 and thus average rupture durations of more than 6 s [ see relationship (3.3)].

According to the above, the difference between  $m_b(\text{IDC})$  and other  $m_b$  values calculated with a more low-frequent response and longer measurement-time window will grow with magnitude. According to Bormann et al. (2007), based on data kindly provided by S. Wendt (2005), the difference between NEIC  $m_b(\text{PDE}) - m_b(\text{IDC})$  is on average:

- 0.06 m.u. for  $m_b(\text{PDE}) < 4.0$
- 0.37 m.u. for  $m_b(\text{PDE}) = 4.0-4.9$ ,
- 0.48 m.u. for  $m_b(\text{PDE}) = 5.0-5.9$ ,
- 0.61 for  $m_b(\text{PDE}) \geq 6$ ,

and reached 1.5 m.u. for the great 2004 Mw9.0 Sumatra-Andaman earthquake.

Granville et al. (2002) analyzed 10 medium-size earthquakes in the depth range 0 km to 530 km and with magnitudes  $m_b$  between 6.4 and 6.8 according to the PDE (Preliminary Determination of Epicenters) reports of the United States Geological Survey (USGS) and 13 underground nuclear tests (UNTs) with PDE magnitudes  $m_b$  between 4.6 and 6.1. They compared these data, which were derived from simulated WWSSN-SP records, by using the traditional procedure of  $m_b$  determination based on the Gutenberg-Richter Q-functions, with a) the  $m_b$  for the same WWSSN-SP data but calibrated with the Veith-Clawson relationship; b) the body-wave magnitudes reported in the REB (Reviewed Event Bulletin) of the (preliminary) PIDC based on the IDC filter with peak magnification around 3.4 Hz. For comparison of the responses see Figure 4 in Granville et al., 2005, or Figure 3 in IS 3.3).

From this study the following conclusions were drawn:

- The agreement between  $m_b(Q)$  (Gutenberg-Richter) and  $m_b(P)$  (Veith-Clawson) based on WWSSN-SP data was still reasonably good for shallow earthquakes (average difference  $m_b(Q) - m_b(P) = 0.2$ );
- For underground explosions (only shallow-depth events!) the agreement was even better (average  $m_b(P) - m_b(Q) = 0.09$ );
- Yet, the average discrepancy between  $m_b(P)$  and  $m_b(\text{PIDC/REB})$  for earthquakes is much larger (0.5 magnitude units), although the latter are also scaled with the Veith-Clawson calibration functions. For 63% of the earthquake observations the difference was at least 0.4  $m_b$  units, and several of them had even an  $m_b$  offset greater than 1 magnitude unit!;
- In contrast, the average discrepancy between  $m_b(P)$  and  $m_b(\text{PIDC/REB})$  for explosions is 0.0 and 75% of the observations fall between  $-0.1$  and  $+0.1$  m.u.;
- The PIDC (now IDC in Vienna) procedure is adequate for  $m_b$  determination of underground nuclear explosions (UNE) and for the discrimination between UNE and

earthquakes on the basis of the mb-Ms criterion but it is not compatible with mb(PDE) or IASPEI standard mb.

### 3.2.6.3 Short-period PKP-wave magnitude

Calibration functions  $Q(\Delta, h)_{\text{PKP}}$  for short-period amplitude and period readings from all three types of direct core phases (PKPab, PKPbc and PKPdf) have been developed by Wendt (see Bormann and Wendt, 1999; also explanations and Figure 3 in DS 3.1). These phases appear in the distance range  $\Delta = 145^\circ - 164^\circ$  (see Fig. 3.34, Figs. 11.62-63 ??? in Chapter 11 and Figure 1 in EX 11.3) with amplitude levels comparable to those of P waves in the distance range  $25^\circ < \Delta < 80^\circ$ . Many earthquakes, especially in the Pacific (e.g., Tonga-Fiji-Kermadec Islands) occur in areas with no good local or regional seismic networks. Often these events, especially the weaker ones, are also not well recorded by more remote stations in the P-wave range but often excellently observed in the PKP distance range, e.g., in Central Europe. This also applies to several other event-station configurations. Available seismic information from PKP wave recordings could, therefore, improve magnitude estimates of events not well covered by P-wave observations at distances below  $100^\circ$ .

Earlier investigations on the use of PKP phases for magnitude determination have been published by Miyamura (1974), Mizone, (1977), Tittel (1977), Janský et al. (1977), Kowalle et al. (1983) and Janský and Kvasnička (1992).

### 3.2.6.4 High-frequency moments and magnitudes

Koyama and Zheng (1985) developed a kind of short-period seismic moment  $M_1$  which is related to the source excitation of short-period seismic waves and scaled to mb according to

$$\log M_1 = 1.24 \text{ mb} + 10.9 \quad (\text{with } M_1 \text{ in } J = \text{Nm}). \quad (3.48)$$

They determined  $M_1$  from WWSSN short-period analog recordings by applying an innovative approximation of spectral amplitudes

$$Y(f) = 1.07 A_{\text{max}} (\tau/f_0)^{1/2} \quad (3.49)$$

with  $A_{\text{max}}$  - maximum amplitude,  $f_0$  - dominant frequency and  $\tau$  - a characteristic duration of the complicated wave-packets. They analyzed more than 900 short-period recordings from 79 large earthquakes throughout the world in the moment range  $7.5 \times 10^{17} \leq M_0 \leq 7.5 \times 10^{22} \text{ Nm}$ .  $M_1$  did not saturate in this range!

More recently, Atkinson and Hanks (1995) proposed a high-frequency magnitude scale

$$\mathbf{m} = 2 \log a_{\text{hf}} + 3 \quad (3.50)$$

with  $a_{\text{hf}}$  as the high-frequency level of the Fourier amplitude spectrum of acceleration in cm/s, i.e., for  $f \gg f_c$ . They use average or random horizontal component accelerometer amplitudes at a distance of 10 km from the hypocenter or from the closest fault segment.  $\mathbf{m}$  has been scaled to the moment magnitude  $\mathbf{M} = M_w$  for events of average stress drop in eastern North America and California. When  $\mathbf{M}$  is known,  $\mathbf{m}$  is a measure of stress drop. For large pre-

instrumental earthquakes  $m$  can more reliably be estimated than  $M$  from the felt area of earthquake shaking (see 3.2.6.6). When used together,  $m$  and  $M$  provide a good index of ground motion over the entire engineering frequency band, allow better estimates of response spectra and peak ground motions and thus of seismic hazard.

### 3.2.6.5 Earthquake early-warning magnitudes

In recent years great attention has been paid to the development of earthquake early warning systems (EEWS) which allow – besides very quick event location - near real-time magnitude estimates from the very first few seconds of acceleration, velocity or displacement records (e.g., Nakamura, 1988. Nakamura and Saita, 2007; Espinoza-Aranda et al., 1995; Teng et al., 1997; Wu et al., 1997; Allan and Kanamori, 2003; Kanamori, 2005; Simons et al., 2006; Zollo et al., 2006; Gasparini et al., 2007). Based on such data rapid public alarms may be issued and/or automatically triggered risk mitigation actions taken between the detection of a strong earthquake at near stations and the arrival of strong ground motion at locations slightly farther away. EEWS aim at minimizing the area of so-called “blind zones” which are left without advanced warning before the arrival of the S waves which have usually the largest strong-motion amplitudes. This necessitates very dense and robust seismic sensor networks within a few tens of km from potentially strong earthquake sources. Such dense networks are at present available or proposed for only a very regions, e.g. in California, Japan, Taiwan, Turkey (Istanbul) and Italy. Their principles of rapid magnitude estimates are rather different from those mentioned above and below and the data analysis from such systems is largely based on much debated concepts such as the hypothesis of the deterministic nature of earthquake rupturing. Olson and Allen (2005), e.g., claim to be able to estimate with an average absolute deviation of 0.54 magnitude units the size of earthquakes up to magnitude 8 from the maximum period of the first arriving P waves within the first 4 s from many low-pass filtered velocity records within 100 km from the epicenter. However, Rydelek and Horiuchi (2006), who analyzed waveform data recorded by the Japanese Hi-net seismic network (see Chapter 8, section 8.7.3), could not confirm that such a dominant frequency scaling with magnitude exists. Also Kanamori et al. (1997), together with Nakamura (1988) one of the fathers of this idea, expressed much more caution about the prospects of this method after they had run together with Wu an extensive experiment with the Taiwan Early Warning System which has presently a 22-s reporting time for first location and magnitude estimates with magnitude uncertainty of  $\pm 0.25$  m.u. (Wu and Kanamori, 2005). To reduce this reporting time even further down to about 8 s and thus the “blind zone”, they used only the records of the first 8 station within less than 21 km epicentral distance to estimated the magnitude via the magnitude dependence of the average period  $\tau_c$  of the P-wave, as well as the peak displacement amplitudes, if  $> 0.1$  cm, within the first 3 s of the low-pass filtered displacement signal after the P-wave onset. Wu and Kanamori (2005) summarized their experience as follows: “... the slip motion is in general complex and even a large event often begins with a small short-period motion, followed by a long-period motion. Consequently, it is important to define the average period ...during the first motion.” However, after applying the  $\tau_c$  concept to the Taiwan EWS they concluded: “...For EWS applications, if  $\tau_c < 1$  sec, the event has already ended or is not likely to grow beyond  $M > 6$ . If  $\tau_c > 1$  sec, it is likely to grow, but how large it will eventually become, cannot be determined. In this sense, the method provides a **threshold warning**”. Moreover: “If  $\tau_c > 1$  sec, the event is potentially damaging. If it is larger than 2 sec, the event is almost certainly damaging. Combining this information with other data, such as the initial velocity and displacement amplitudes, would allow the damage potential of the event to be assessed more accurately.” More can indeed not

be expected to be said within the first 3 s of a record, especially not for strong and great earthquakes. Only for earthquakes with  $M \leq 6$  and thus total rupture durations that are according to formula (3.5) on average not more than about twice the  $\tau_c$  measurement time windows of Kanamori (3 s) or Olson and Allen (4 s), these new concepts seem to yield reasonably good magnitude estimates, comparable with those provided by tsunami early warning systems (TEWS) in the case of strong to great tsunamigenic earthquakes within some 5 to 30 min (e.g., Lomax and Michelini, 2012). This is illustrated by short reference to and discussion of several representative EEWS.

The Nakamura UrEDAS (Urgent Earthquake Detection and Alarm System) predicts the magnitude from the dominating period  $T_d$  within a few seconds of the initial P-wave motion. According to Nakamura and Saita (2007) these dominating periods, when observed at hypocentral distances between about 50 to 850 km, increase for earthquakes with  $M_{JMA}$  3 to 7 from an average of about 0.2 s to 4 s. However, due to the large scatter of  $T_d$  by a factor of about 3 measured at individual stations for the same event, the event magnitude  $M_{JMA}$  can only be estimated with a possible error of about 0.5 m.u.

The ElarmS system (Allen and Kanamori, 2003), an adaptation of UrEDAS for Southern California, uses TriNet and California Integrated Seismic Network stations (see IS 8.4, and Simons et al., 2006). For estimating the magnitude it measures the **predominant period**  $T_{max}^P$  (between 0.1 and 3 s) in broadband velocity records within the first few seconds (1 to 4 s, depending on event size) after the P-wave onset. Yet, again due to the large variability of the individual station  $T_{max}^P$  (up to a factor of about 10) the average absolute error in the estimated magnitude is  $\pm 0.7$  m.u. when measured only at the closest station to the epicenter. However, when the closest 10 stations within 100 km of the epicenter are used, this error drops to  $\pm 0.35$  m.u. Allen and Kanamori (2003) give two regression relationships for estimating the magnitude via  $T_{max}^P$ , one for events with magnitudes between 3 and 5, the other one for magnitudes between 4.5 and 7.

Grecksch and Kämpel (1997) estimated the magnitudes using the rise time of the first complete peak amplitude, the **predominant period**, and the related Fourier amplitude of the initial part of strong-motion signals. Yet, with this approach the magnitude uncertainty may even be as large as  $\pm 1.35$  m.u. with a single accelerogram and  $\pm 0.5$  m.u. with more than eight accelerograms.

A different approach had been taken by Wu et al. (1998). Using strong-motion records from moderate size earthquakes with  $5.0 \leq M_l \leq 6.5$  and 10 s waveforms after the P-wave onset they derived an  $M_{l10}$  estimator from the strong-motion signal duration which allows to estimate local magnitude  **$M_l = 1.28M_{l10} - 0.85 \pm 0.13$**  with a correlation coefficient of 0.96. The slope of 1.28 indicates that small earthquakes require smaller and bigger earthquakes larger adjustments at 10 s to be made. With this procedure the Taiwan Central Weather Bureau determines epicenters and rather reliable magnitudes in about 20 to 30 s after the occurrence of moderate size earthquakes.

For larger crustal earthquakes Wu and Teng (2004) developed another method of estimating the moment magnitude with a standard deviation of about  $\pm 0.30$  m.u. up to magnitudes of about 7.5 by integration of near source strong-motion amplitudes over the **whole rupture duration**. Yet, such magnitude estimates require more time, and are available only within some 30 to 60 s after origin time. This time lag is not suitable for advanced early warning anymore, however quite adequate for rapid response services (RRS).

In order to reduce the time lag Wu and Zhao (2006) again dealt with estimating the magnitude by using the **P-wave amplitudes** within the first three seconds of the record. Applied to earthquakes in Southern California they found out that their “*Pd magnitudes*” agree with catalog magnitudes with a **standard deviation of  $\pm 0.18$  m.u. for events with magnitudes  $< 6.5$**  but that they saturate for larger ones and can not be used to estimate magnitudes  $\geq 6.7$ . The same problem of saturation of *Pd* amplitudes they had observed already for large earthquakes in Taiwan (Wu et al., 2006), thus providing evidence that the deterministic earthquake initiation model of Olson and Allen (2005) is not applicable to large earthquakes with magnitudes up to 8 and more, with rupture durations up to several 100 s.

In Italy, with very dense accelerometer networks near to major active faults, a procedure has been developed and tested by Zollo et al. (2006) which determines for both P and S waves the distance corrected logarithm of peak displacement ( $\log(\text{PGD}_t^{10\text{km}})$ ) within the first 2 s after the onset of P and S for events in the magnitude range between 4 and 7.3 (93% in the range 4 to 6). Most of the records have been made at distances less than 20 km from the source. The authors give weighted standard for their  $\log\text{PGD}$  estimates of  $\pm 0.13$  (for S) to  $\pm 0.22$  (for P).

A very different approach has been taken by Simons et al. (2006). They determine the earthquake magnitude via a multiscale wavelet analysis from the first 3-4 s of the incoming P wave and analyzed 2272 seismograms recorded by the Southern California TriNet array at epicentral distances up to 150 km in the magnitude ranges from 3 to 5 and  $> 5$  to 7.3, respectively, as in Allen and Kanamori (2003). Yet also they could predict the true magnitude only within approximately one unit. These authors correctly state that “...the nature of wave propagation (which includes the effects on the P-wave amplitude due to focusing, attenuation and site amplification) as well as the complexities of the source mechanism, and its orientation with respect to the measurement stations, are all such that any predictive relationships between the observables gleaned from the P wave and earthquake magnitude are statistical at best.”

This notwithstanding, much of the average potential as well as the principal shortcomings of the above EEW magnitude procedures could have been predicted and wrong claims as those by Olson and Allen (2005) be avoided by taking into account the approximate relationship (3.5) as well the average seismic source spectra in Fig. 3.5 of this Chapter.

According to relationship (3.5) the average rupture duration of magnitude  $M = 3$  events is  $\approx 0.1$  s, for  $M = 5 \approx 1.6$  s, for  $M = 6 \approx 6$  s, and for  $M \geq 7 \approx 25$  s up to about 400 s for  $M = 9$ . Moreover, the large and great earthquakes are usually very individual multiple rupture processes with complicated and often non-symmetric source-time functions (see, e.g., Figs. 3.5, 3.9 3.10, 3.13 in this Chapter). This may even require to approximate the moment-rate release function by multiple point sources to get correct  $M_w$  estimates (e.g., as Tsai et al., 2005, for the great 2004 Sumatra-Andaman earthquake). In view of these facts, to speak of a deterministic nature of earthquake ruptures which allows to predict their size up to magnitude 8 from data within the first 4 s of a seismic records is daring. At best one can speak of a deterministic component in the rupture process. Suitable measurement parameters related to this deterministic component are the average **rupture duration**, uncertain by a factor of about 2-3 for a given event and magnitude (see, e.g., Fig. 3.5), and the approximate average corner frequency  $f_c$  of the source spectrum, also with a variability range at a given magnitude due to variations in stress drop and/or rupture velocity.

Moreover, magnitude is supposed to be an estimator of released seismic energy. The largest amount of energy is released around  $f_c$ . According to Fig. 3.5, right-hand panel,  $f_c$  is on average for  $M_w = 3 \approx 10$  Hz, for  $M = 5 \approx 1$  Hz, for  $M = 6 \approx 0.3$  Hz, and the respective corner periods for  $M = 7, 8$  and  $9 \approx 25$  s, 100s and 400 s, respectively. But this means that up to  $M = 6$  the dominating radiated periods are already contained in the first few second of the P-wave record. And since the rupture duration for  $M = 6$  is on average only about 6 seconds, the related amplitude maximum will also appear within a time window of 3-4 s after the P-wave onset, a symmetric moment rate release function provided. Thus there is no wonder, why the EEW magnitude procedures based on  $P_d$  and/or  $\tau_c$  work reasonably well up to magnitudes 6-6.5, begin to saturate, however, for stronger earthquakes. And then it is understandable, why the strong-motion duration-based procedure by Wu and Teng (1998) works fine up to 7.5 when integrating over time windows between 30 s and 60 s.

And beyond, this principle discussion explains also why procedures as proposed, e.g., by Hara (2007 a and b), Bormann and Saul (2009), and Lomax and Michelini (2009 a and b) do not saturate at all. They relate maximum, summed-up or integrated amplitudes or, as Lomax and Michelini (2011 and 2012) the dominant period  $T_d$  (up to 30 s and more) to estimates of the rupture duration. Lomax and Michelini (2012) even measure  $T_d$  by the peak of the  $\tau_c$  algorithm of Nakamura (1988) and Wu and Kanamori (2005), applied with a 5 s sliding time-window from 0 to 55 s after the P arrival on velocity seismograms. I.e., essentially the same measurement parameters are looked for as by the EEW community, but they avoid saturation by adopting the measurement time window after P to the growing rupture duration and the bandwidth of the record so as to surely cover  $f_c$  and thus  $P_d$ . And additionally, as by Wu et al. (1998) for magnitudes up to 7.5, the rupture duration itself is taken into account. Yet such principle considerations can not be found in any of the other above referenced EEW papers.

### 3.2.6.6 Macroseismic magnitude

In order to apply the useful concept of instrumentally determined magnitudes for earthquake size classification, statistics and seismic hazard assessment also to earthquakes that occurred in the pre-instrumental era, relationships between earthquake magnitudes and macroseismic parameters determined in the instrumental era had to be developed. Some of these efforts aimed at developing specifically magnitude scales which are best suited for earthquake engineering assessment of potential damage and thus seismic risk. According to Grünthal (2011) “intensity data give a surprisingly robust measure of earthquake magnitudes.” These efforts go in two directions: by relating  $M$  to macroseismic intensity  $I$  and/or shaking area  $A_I$  or by focusing on the high-frequency content of seismic records.

*Macroseismic magnitudes*,  $M_{ms}$  are particularly important for the analysis and statistical treatment of historical earthquakes. Gutenberg and Richter (1942) published already a few years after the introduction of the instrumental earthquake magnitude by Richter (1935) a first empirical relationship with the epicentral intensity  $I_0$  followed by Kawasumi (1951) who related his magnitude scale  $M_K$  to the **intensity  $I$  in the JMA scale** (see Chapter 12) **at the 100 km distance**, following Richter’s definition of  $M_I$  as closely as possible. This approach is physically quite reasonable because for most earthquakes a distance of 100 km is already the far field and source finiteness can be ignored. The Kawasumi intensity-magnitude conversion formula reads:

$$M_K = 0.5 I_{100} + 4.85. \quad (3.51)$$

This approach was further developed by Rautian et al. (1989).

Other approaches related either the maximum observed intensity  $I_{\max}$  (e.g., Topozada, 1975) or the epicentral intensity  $I_0$  to  $M$  (e.g., Karnik, 1969). Differences between  $I_0$  and  $I_{\max}$  are expected to be small, but there have been instances where  $I_{\max}$ , due to extreme local site effects exceeded  $I_0$  as much as two degrees (Tinti et al., 1987). Therefore, relationships based on  $I_0$  are nowadays generally preferred to  $I_{\max}$ -based relationships. On the other hand,  $I_0$ -based definitions implicitly assume the point source model and must be often misleading. Of course, with historic catalogs, there is usually no other way. There are three main approaches to compute macroseismic magnitudes:

- 1)  $M_{ms}$  is derived from the epicentral intensity  $I_0$  (or the maximum reported intensity,  $I_{\max}$ ) assuming that the earthquake effects in the epicentral area are more or less representative of the strength of the event (e.g., Karnik, 1969);
- 2)  $M_{ms}$  is derived from taking into consideration the whole macroseismic field, i.e., the size of the shaking is related to different degrees of intensity or the total area of perceptibility,  $A$  (e.g., Topozada, 1975);
- 3)  $M_{ms}$  is related to the product  $P = I_0 \times A$  which is nearly independent of the focal depth,  $h$ , which is often not reliably known (Toperczer, 1953).

Accordingly, formulae for  $M_{ms}$  have the general form of

$$M_{ms} = a I_0 + b, \quad (3.52)$$

or, whenever the focal depth  $h$  (in km) is known, which strongly controls  $I_0$ ,

$$M_{ms} = c I_0 + \log h + d, \quad (3.53)$$

or, when using the shaking area  $A_{li}$  (in  $\text{km}^2$ ) instead,

$$M_{ms} = e \log A_{li} + f \quad (3.54)$$

with  $A_{li}$  in  $\text{km}^2$  shaken by intensities  $I_i$  with  $i \geq \text{III}$ , ..., VIII, respectively.

Since dominating source depth and intensity-attenuation conditions may vary significantly from region to region, the relevant coefficients have to be determined regionally. E.g., in order to derive suitable relationships according to (3.52) for Italy, Tinti et al. (1987) had to subdivide the territory into eight distinct regions for which the constant  $a$  varies between 0.27 and 0.62 and the correlation coefficients between 0.79 and 0.92. Karnik (1969) published a widely used relationship according to (3.53) for Europe:

$$M_{ms} = 0.5 I_0 + \log h + 0.35. \quad (3.55a)$$

Gutdeutsch et al. (2002), however, derived another **orthogonal** regression relationship for Central and Southern Europe, which differs considerably from Karnik's formula:

$$M_{ms} = 0.654 I_0 + 1.868 \log h - 1.682 \quad \text{with SD} = \pm 0.284. \quad (3.55b)$$

For a given magnitude,  $I_0$  depend on source depth  $h$ . Two extreme examples from Illionois earthquakes have been referred to by Nuttli et al. (1979): The same  $I_0 = VII$  has been observed both by an earthquake with  $mb = 3.8$  at  $h = 1$  km source depth and by another one with  $mb = 5.5$  at 20 km depth.

In the above equations,  $M_{ms}$  is used for a generic macroseismic magnitude. Musson and Ceci  (2002) emphasize, however, that for any particular equation it is important to specify what type of magnitude the equation is compatible with ( $M_w$ ,  $M_l$ ,  $M_s$ , or others). Moreover, it is also important to determine the standard error as a measure of uncertainty attached to the estimated magnitude values, as for the relationship (3.55b).

Relationships of the form of equation (3.54), with the area of intensities of shaking from IV to VIII scaled to local magnitude  $M_l$ , have been developed by Topozada (1975) for California and Western Nevada.

Sometimes the mean radius  $R_{ii}$  of the shaking area related to a given isoseismal intensity is used instead of the area  $A_i$  and (3.52) is then written:

$$M_{ms} = g \log R_{ii}^2 + h \log R_{ii} + j. \quad (3.56)$$

Greenhalgh et al. (1989) give such relationships for the radii of Modified Mercalli (MM) intensities III and IV as observed for Australian earthquakes and with  $M_{ms}$  scaled to  $M_l$ .

Thus, in the above relationships, the constants **a** through **j** have to be determined independently for different regions and accordingly,  $M_{ms}$  is mostly scaled to local/regional  $M_l$ . Also  $M_l$  requires local/regional scaling and has proven to be best related to earthquake damage and engineering applications because of  $A_{max}$  being measured in the most relevant frequency range for earthquake engineers between about 0.5 to 10 Hz. Yet, some  $M_{ms}$  relationships in the United States have been scaled instead to the near 1-Hz  $mb(Lg)$ , e.g. by Street and Turcotte (1977) for the Northeastern North America and by Nuttli et al. (1979).

In recent years, however, it has become increasingly fashionable to unify magnitudes in earthquake catalogues to the moment magnitude  $M_w$  (for criticism see 3.2.10), although  $M_w$  is a static measure of earthquake size and derived from the long-period asymptotic plateau of the radiated source displacement spectrum instead of being measured around its corner frequency at which the maximum of seismic energy is radiated. Yet, as long as the considered magnitudes  $M_w < 6.5$  and thus the corner frequencies according to Fig 3.5 on average  $> 0.3$  Hz such an approach may still be acceptable, not, however, when much larger or slow earthquakes play a significant role in the area under consideration.

Gr nthal et al. (2009) published such a relationship based on well constrained moment magnitude  $M_w$ ,  $I_0$ , and  $h$  of European earthquakes. It reads

$$M_w = 0.667 I_0 + 0.30 \log(h) - 0.10, \quad (3.57)$$

or, when no reliable information about  $h$  is available

$$M_w = 0.682 I_0 + 0.16. \quad (3.58)$$

These two relations are valid in the ranges  $5 < I_0 < 9.5$ ,  $3.0 < M_w < 6.4$ , and  $5 \text{ km} \leq h < 22 \text{ km}$ .

According to Musson and Cčić (2002), differences in spectral content for larger earthquakes may affect the way in which earthquake vibration is perceived, and a different scaling with area appears then to apply. Therefore, Frankel (1994) uses for representing the full magnitude range the form

$$M_{ms} = n \log(A/\pi) + 2m/(2.3\sqrt{\pi})\sqrt{A} + a \quad (3.59)$$

where  $n$  is the exponent of geometrical spreading,  $m = (\pi f)/(Q\beta)$  with  $f$  = predominant frequency of earthquake motion at the limit of the felt area (probably 2-4 Hz),  $Q$  the shear-wave attenuation, and  $\beta$  = shear-wave velocity, taken as 3.5 km/s).

Frankel (1994) compared felt area and moment magnitudes for California with its young mountain ranges with a global data set of earthquakes in stable continental regions (SCRs) such as central USA (Fig. 3.57). The main reason for the large difference in felt area for equal moment magnitude  $M_w$  is that the average attenuation is at frequencies around 2-4 Hz, which is the range of best human perceptibility to ground shaking, much higher in California than in SCRs, with corresponding  $Q$  values of about 490 in California and 1600 in SCRs, respectively.

**Fig. 3.57** Felt area  $A_f$  (in  $\text{km}^2$ ) plotted against moment magnitude,  $M_w$ , for global data from stable continental regions (SCR) (open circles; from Johnston, 1993) and California data (triangles, from Hanks et al., 1975; Hanks and Johnston, 1992). Solid and dashed lines are fits according to an equation given by Frankel (1994) (modified from Frankel, Implications of felt area-magnitude relations for earthquake scaling and the average frequency of perceptible

ground motion, Bull. Seism. Soc. Am., Vol. 84, No. 2, Fig. 1, p. 463, 1994; © Seismological Society of America).

Johnston (1996) derived a regression relation for the Modified Mercalli Intensity scale (MMI; see Chapter 12) for stable continental regions to predict seismic moments  $M_0$  according to the functional regression form (3.59) proposed by Frankel (1994) with an uncertainty in the range of  $\pm 0.15$  to  $0.23$   $M_w$  units, and another  $M_{ms}$  scale based on  $P = I_0 \times A$  (in  $\text{km}^2$ ) had been published by Galanopoulos (1961):

$$M_{ms} = \log P + 0.2 (\log P - 6), \quad (3.60)$$

A macroseismic magnitude scaled to the body-wave magnitude of Central United States earthquakes in the range  $2.7 \leq mb \leq 5.5$  was developed by Nuttli and Zollweg (1974):

$$mb = 2.65 + 0.098 \log A_f + 0.054 (\log A_f)^2. \quad (3.61)$$

It is applicable for magnitude estimates of central United States earthquakes with felt areas of shaking  $A_f \leq 10^6 \text{ km}^2$  for which there are intensity maps but no instrumental data available.

Other forms of these equations combine  $I_0$  and the radius  $r$  of the total macroseismic field (Albarelo et al., 1995), either in the way

$$M_{ms} = a I_0 + b \ln r + c, \quad (3.62a)$$

or, when using values for each available isoseismal  $I$ ,

$$M_{ms} = a I_0 + \sum b_i \ln r_i + c. \quad (3.62b)$$

However, because of the subjectivity in isoseismal construction, modern opinion favours the direct use of the distribution of intensity  $I$  data points (IDPs) at epicentral distance  $D$ , without any isoseismals. This is particularly suitable in the case of sparse intensity data. An example are the two formulas given by Braunmiller et al. (2005) for earthquakes in Switzerland:

$$M_{ms} = [I(D) - 0.096 + 0.043D]/1.27 \quad \text{for shallow earthquakes (h} \approx 5 \text{ km)} \quad (3.63a)$$

and

$$M_{ms} = [I(D) + 1.173 + 0.030D]/1.4 \quad \text{for deeper earthquakes (h} \approx 12 \text{ km)}. \quad (3.63b)$$

Currently three systems are available for the joint computation of the main earthquake parameters epicentre/hypocenter and magnitude from IDP sets: The Bakun-Wentworth (B-W) method, originally developed for California by Bakun and Wentworth (1997), the BOXER method for Italian earthquakes with  $M_s > 5.5$  by Gasperini et al. (1999) and MEEP (Macroseismic Estimation of Earthquake Parameters) by Musson and Jiménez (2008). In Chapter 12 (Fig. 12.8) of this Manual, Musson and CeciĆ compare the results of all three methods, applied to the same IDP set of an earthquake in the UK, with the instrumentally calculated epicentre and magnitude. All these methods require a well-calibrated intensity-attenuation model valid for the region under consideration.

A related problem is the determination of magnitudes of prehistoric and historic (pre-instrumental) earthquakes from dimensions (length  $L$ , width  $W$  and/or dislocation  $D$ ) of

observed seismo-dislocations (e.g., Khromovskikh, 1989; Wells and Coppersmith, 1994; Mason, 1996) based on correlation relationships between magnitudes and respective field data from recent events (see 3.3.4).

### 3.2.6.7 Tsunami magnitude

A different kind of magnitude is the tsunami magnitude scale  $M_t$  as defined by Abe (1979 and 1981b). The scale is so constructed that  $M_t$  agrees with the moment magnitude  $M_w$ . According to Abe (1989) holds

$$M_t = \log H_{\max} + a \log \Delta + C \quad (3.64)$$

where  $H_{\max}$  is the maximum single (crest or trough) amplitude of tsunami waves in m as measured by tide-gage records and /or as derived from maximum inundation height,  $\Delta$  - epicentral distance in km to the respective tide station and  $a$  and  $C$  - constants ( $a$  was found to be almost 1). In case of the long-wave approximation, i.e., with tsunami wavelengths being much larger than the bathymetric depths, the maximum tsunami height is strictly related to the maximum *vertical* deformation of the ocean bottom,  $D_{\perp \max}$ , and thus to the seismic moment  $M_0$ .  $M_t$  was calibrated, therefore, with the average condition  $M_t = M_w$  for the calibration data set. This resulted in:

$$M_t = \log H_{\max} + \log \Delta + 5.8. \quad (3.65)$$

(3.65) shows no saturation. For the Chile earthquake 1960  $M_t = 9.4$  while  $M_w = 9.5$ . Sometimes, very slow but large ruptures with a large seismic moment cause yet much stronger tsunami than would have been expected from their moment, surface wave, energy or body-wave magnitudes  $M_w$ ,  $M_s$ ,  $M_e$  or  $m_b$ , respectively. Such events are called "tsunami earthquakes" (Kanamori, 1972; Kanamori and Kikuchi, 1993; Polet and Kanamori, 2009). A striking example is the April 1, 1946 Aleutian earthquake with  $M_s = 7.3$ ,  $M_w = 8.6$  and  $M_t = 9.3$ .  $M_t$  avoids this underestimation of possible tsunami effects of such earthquakes by the common magnitude scales. Hara (2007b) gives two more examples for the 1992 Nicaragua earthquake ( $M_w = 7.6$ ,  $M_t = 8.0$ ) and the 1996 Peru earthquake ( $M_w = 7.5$ ,  $M_t = 7.8$ ). Such earthquakes have negligibly small energy in the high-frequency range and cause little or no shaking damage (see discussions in section 3.2.7.2 on energy magnitude  $M_e$ ).

## 3.2.7 Non-saturating magnitude scales $M_w$ and $M_e$

### 3.2.7.1 Moment magnitude $M_w$ (P. Bormann)

The history of the derivation of the moment magnitude scale and the essential assumptions on which it is based have been outlined in detail by Bormann and Di Giacomo (2011) and in 3.1.2.5. Here we summarize only the essentials.

According to Eq. (3.2) and Fig. 3.5 the scalar seismic moment  $M_0 = \mu \bar{D} A$  is determined from the asymptote of the displacement amplitude spectrum as frequency  $f \rightarrow 0$  Hz. If this condition is fulfilled  $M_0$  does not saturate. Kanamori (1977) proposed, therefore, a moment magnitude,  $M_w$ , which is tied to  $M_s$  but which would not saturate either. He reasoned as follows: According to Kostrov (1974) the radiated seismic strain energy is proportional to the

stress drop  $\Delta\sigma$ , namely  $E_s \approx \Delta\sigma \bar{D} A/2$ . With Eq. (3.2) one can write  $E_s \approx (\Delta\sigma/2\mu) M_0$ . (For definition and determination of  $M_0$  and  $\Delta\sigma$  see also IS 3.1 and EX 3.4). Assuming a reasonable value for the shear modulus  $\mu$  in the crust and upper mantle (about  $3\text{--}6 \times 10^4$  MPa) and assuming that, according to Kanamori and Anderson (1975) and Abe (1975), the stress drop of large earthquakes is remarkably constant (ranging between about 2 and 6 MPa; see Fig. 3.37), one gets as an average  $E_s \approx M_0/2 \times 10^4$  (see Fig. 3.88). Inserting this into the relationship proposed by Richter (1958) between the released seismic strain energy  $E_s$  and  $M_s$ , namely

$$\log E_s = 4.8 + 1.5 M_s \text{ (in SI units Joule J = Newton meter Nm)} \quad (3.66)$$

it follows:

$$\log M_0 = 1.5 M_s + 9.1, \quad (3.67)$$

which holds, however, according to empirical data by Ekström and Dziewonski (1988), for  $M_s > 6.8$  only.

Solving (3.67) for the magnitude and replacing  $M_s$  with  $M_w$  one gets with  $M_0$  in Nm

$$M_w = (\log M_0 - 9.1)/1.5 = (2/3) (\log M_0 - 9.1) \quad (3.68)$$

and  $M_w = M_s$  for  $M_s > 6.8$ . This has been proved to be essentially correct by more recent empirical  $M_w$ - $M_s$  regression relationships with slopes of 0.94 between  $6.5 < M_s < 8.8$  (Bormann et al., 2009), 0.99 between  $6.2 \leq M_s \leq 8.2$  (Scordilis, 2006), 1.06 between  $6.2 < M_s \leq 8.4$  (Das et al., 2011) and 1.10 for  $M_s$  between 6.5 and 8.7 (Di Giacomo et al., 2013b). Formula (3.68) is now the IASPEI (2005 and 2013) accepted standard form of writing the moment magnitude formula. It avoids rounding errors and an ambiguity that arises if multiplication is performed prior to subtraction, which in a certain percentage of cases leads to  $M_w$  being different according to whether the moment is expressed in CGS or SI units (Utsu, 2002, and IS 3.3).

$M_0$  and  $M_w$  scales well with the logarithm of the rupture area [see Eqs. (3.165-3.167) and Figs. 3.94 and 3.95]. The determination of  $M_0$  on the basis of digital broadband records is becoming increasingly standard at modern observatories and network centers. Yet, the source spectra of small to moderate earthquakes with magnitudes  $< 5$  have usually corner frequencies higher than 0.5 Hz (see Fig. 3.5) and are often recorded at local to near regional distances with short-period instruments only.  $M_0$  is then usually obtained in the spectral domain by determining the spectral plateau amplitude  $u_0$  and using formula (3.2) (e.g., EX 3.4). For stronger up to great earthquakes ( $M > 8$ ) however, recorded at teleseismic distances and much longer wavelengths, least-square waveform fitting of synthetic to long-period filtered seismograms is the preferred procedure. Dziewonski et al. (1981) developed such an algorithm for the full inversion of moment tensors from long-period body- and surface-waveforms with periods up to 45 s and 135 s, respectively. The automated version, which has become known as the Harvard Centroid Moment Tensor project and since 2006 as the Global CMT (<http://www.globalcmt.org/>), also yields the scalar seismic moment  $M_0$  and  $M_w$  as spin-off parameters. This method is still used, with some upgrading, e.g. those aiming at faster and more reliable solutions for very great complex mega-earthquakes. For such events the Harvard CMT moments turned out to be systematically too low because the longest periods considered were below the corner period of the single point source spectrum and the algorithm did not provide for fitting multiple source moment release functions (Stein and

Okal, 2005; Tsai et al., 2005). Provisions have now been made to use longer periods for megathrust earthquakes. GCMT catalog data for events with  $M_w > 5.5$  are considered to be available rather complete since 1977 but in more recent times also available down to  $M_w \approx 4.5$ , although incomplete (see Figs. 3.81 and 3.82). For a most recent review about this project see Ekström et al. (2012).

Besides the GCMT also other agencies offer CMT solutions routinely for global and/or regional seismic events, such as the USGS NEIC, the GEOFON Big Alert Service of the GFZ German Research Centre for Geosciences (<http://geofon.gfz-potsdam.de/eqinfo/gevn>), the Swiss Earthquake Service (SED), the Japan Meteorological Survey (JMA), the Geophysical Survey of the Russian Academy of Sciences in Obninsk, to name just a few. In general, however,  $M_0$ , published by different authors or agencies, depends on details of the individual inversion methodologies and thus related event  $M_w$  may differ. Several alternative algorithms sharing the waveform inversion approach have been developed, e.g., by Aki and Patton (1978) and Kanamori and Given (1981) using surface waves and by Langston (1981), Sipkin (1982: 1986); and Nabelek (1984) using body waves. The USGS moment tensor solutions according to Sipkin (1986) use 15-55 s passband filtered waveform data. Therefore, this procedure also underestimates  $M_w$  for really great earthquakes. The code of Ammon (2001), developed for use on smaller magnitude earthquakes, works well with bandpass filtered waveform data between some 20 and 50 s. Thus,  $M_w$  methodologies and results have also to be critically checked for the range of their non-saturating applicability. For a detailed summary on the theory and methodologies of seismic moment tensor solutions and available services see IS 3.8, IS 3.9, and related exercises EX 3.5 and 3.6.

### 3.2.7.2 Energy magnitude $M_e$ (D. Di Giacomo and P. Bormann)

Also the energy magnitude  $M_e$  is in principle a non-saturating magnitude, provided that it can be measured by covering a sufficiently wide range of spectral velocity amplitudes. Bormann and Di Giacomo (2011) outlined in detail the common roots of  $M_e$  and  $M_w$  as well as their differences both in theory and practical application (see also 3.1.2.5). In the following we recapitulate the essentials.

According to Kanamori (1977)  $M_w$  agrees very well with  $M_s$  for many earthquakes with a rupture length of about 100 km. Furthermore, he suggested that the  $\log E_s$ - $M_s$  relationship Eq. (3.66) also gives a correct value of the radiated seismic-wave energy for earthquakes with rupture dimensions larger than about 100 km. Therefore, Kanamori considered the  $M_w$  scale to be a natural continuation of the  $M_s$  scale for larger events. Thus, when inserting into Eq. (3.66) the value of  $M_w = 9.5$  for the Chile 1960 earthquake instead of the saturated value  $M_s = 8.5$  one gets a seismic energy release that is 30 times larger.

When substituting in Eq. (3.66) the surface-wave magnitude  $M_s$  by an energy magnitude  $M_e$ , it follows

$$M_e = (\log E_s - 4.8)/1.5 = (2/3) (\log E_s - 4.8). \quad (3.69)$$

In the case that Kanamori's condition  $E_s/M_0 \approx 5 \cdot 10^{-5}$  holds, Eq. (3.69) reduces to  $M_e = (2/3) (\log M_0 - 9.1) = M_w$ . The latter has been published earlier by Purcaru and Berckhemer (1978), yet is valid only for the average apparent stresses (and related stress drop) on which the Kanamori condition is based. However, Choy and Boatwright (1995) showed that apparent stress, which is related to the ratio of  $E_s/M_0$ , may vary even for shallow events over a

wide range between about 0.03 and 20.7 MPa. For deep earthquakes, the range is between about 0.03-7.4 MPa. They also found systematic variations in apparent stress as a function of focal mechanism, tectonic environment, and seismic setting. Oceanic intraplate and ridge-ridge transform earthquakes with strike-slip mechanisms tend to have higher stress drop and  $E_s/M_0$  ratio than interplate thrust earthquakes, with fault maturity obviously playing a major role (see IS 3.5). Accordingly,  $M_e$  for the former will often be significantly larger than  $M_w$ . The opposite will be true for the majority of thrust earthquakes in subduction zones, for which  $M_w$  will be larger than  $M_e$ . Therefore, Choy (2012) proposed  $\Delta M = M_e - M_w$ , termed “differential magnitude”, as a useful diagnostic parameter to discriminate between earthquakes with unusually high, intermediate and anomalously low energy radiation (see Figure 5 in IS 3.5). This point had repeatedly been made already in earlier publications (see next paragraph).

Riznichenko (1992) gave a correlation on the basis of data from various authors. It predicts (despite rather large scatter) an average increase of  $\Delta\sigma$  with source depth  $h$  according to  $\Delta\sigma = 1.7 + 0.2 h$ , i.e., stress drops even larger than 100 MPa can be expected for very deep earthquakes. On the other hand, Kikuchi and Fukao (1988) found from analyzing 35 large earthquakes in all depth ranges that  $E_s/M_0 \approx 5 \cdot 10^{-6}$ , i.e., a ratio that is one order of magnitude less than the condition used by Kanamori for deriving  $M_w$ . Therefore,  $M_e$  is not uniquely determined by  $M_w$ . Rather,  $M_e$  and  $M_w$  are complementary descriptions of earthquake size and can be considerably different, up to 1 m.u. and even more. Striking examples have been published by Choy and Kirby (2004), Di Giacomo et al. (2010a), Bormann and Di Giacomo (2011) and by G. Choy in IS 3.5 of this Manual.

The difference between  $M_w$  and  $M_e$  reflects that  $M_w$  is nothing but a static measure of earthquake size [see relationship (3.1)] and thus of its overall tectonic effect. Thus,  $M_w$  does not contain any information about the dynamics of the source process. In contrast,  $M_e$  is mainly controlled by the latter, namely by differences in stress drop and rupture velocity, which have a direct bearing also on the dominating frequency content of the radiated seismic energy (see also section 3.1.2.5).

Nowadays, with digital broadband recordings and fast computer programs, it is feasible to determine directly the seismic energy,  $E_s$ , by integrating the radiated energy flux in velocity-squared seismograms over the duration of the source process and correcting it for the effects of geometric spreading, attenuation and radiation pattern. According to Di Giacomo and Bormann (2011), via Venkatamaran and Kanamori (2004), it holds

$$\begin{aligned}
 E_s &= \left( \frac{1}{15\pi\rho\alpha^5} + \frac{1}{10\pi\rho\beta^5} \right) \int_{-\infty}^{\infty} \left| \hat{\dot{M}}(f) \right|^2 df \\
 &= \left( \frac{2}{15\pi\rho\alpha^5} + \frac{1}{5\pi\rho\beta^5} \right) \int_0^{\infty} \left| \hat{\dot{M}}(f) \right|^2 df \\
 &\approx \left( \frac{2}{15\pi\rho\alpha^5} + \frac{1}{5\pi\rho\beta^5} \right) \int_{f_1}^{f_2} \left| \hat{\dot{M}}(f) \right|^2 df
 \end{aligned} \tag{3.70}$$

where  $\rho$  = density,  $\alpha$  and  $\beta$  =  $P$ - and  $S$ -wave velocities of the medium,  $\hat{\dot{M}}(f)$  = derivative of the seismic moment rate,  $f$  = frequency and  $f_1$  and  $f_2$  the lower and upper bounds of the integration, respectively.

A method, developed by Boatwright and Choy (1986) is now routinely applied at NEIC to compute radiated energies for shallow earthquakes of  $m_b > 5.8$  (see IS 3.6). Its application is not so trivial and not for use with single stations. Using almost 400 events, Choy and Boatwright (1995) derived the relationship for  $E_S$ - $M_s$  as

$$\log E_S = 1.5 M_s + 4.4. \quad (3.71)$$

It indicates that (3.66) slightly overestimates  $E_S$ . On the basis of such direct energy estimates these authors developed the energy magnitude relationship

$$M_e = (2/3) (\log E_S - 4.4) \quad (3.72)$$

For earthquakes satisfying Kanamori's condition  $E_S/M_0 \approx 5 \cdot 10^{-5}$

$$M_e = 2/3 \log M_0 - 5.80 = M_w + 0.27 \quad (3.73)$$

i.e., an  $M_e$  that is even larger than  $M_w$ . The Kanamori condition, however, is a narrow case.

To the contrary, according to the global average ratio  $E_S/M_0$  in Choy et al. (2006) the average difference is  $\Delta M = M_e - M_w = -0.16$  and with respect to the newest data compilation in Figure 5 of IS 3.5 even less ( $\Delta M = -0.36$ ), which corresponds to  $E_S/M_0 = 5.75 \cdot 10^{-6}$  instead of  $E_S/M_0 \approx 5 \cdot 10^{-5}$  assumed by Kanamori (1977) for deriving the  $M_w$  formula and in very good agreement with the  $E_S/M_0 \approx 5 \cdot 10^{-6}$  by Kikuchi and Fukao (1988).

$\Delta M$  may become even much more negative, down to almost -1.5, for slow “tsunami earthquakes”, corresponding to  $E_S/M_0 \approx 1 \cdot 10^{-7}$ . The latter may generate a strong (namely long-period) tsunami but only weak short-period ground motion, which may cause no shaking-damage and might not even be felt by people in the near field of the rupture. This has repeatedly been the case, e.g., on September 2<sup>nd</sup>, 1992 with the  $M_w 7.6$  Nicaragua earthquake, which had only an  $m_b = 5.3$  and an  $M_e = 6.7$ , on June 2<sup>nd</sup>, 1994 with the  $M_w 7.8$  Java tsunami earthquake with reported values for  $M_e$  between 6.5 and 6.8, and on July 17<sup>th</sup>, 2006 with the  $M_w 7.7$  Java earthquake with  $M_e = 6.8$ . Moment-wise, all three earthquakes were comparably large, yet their rupture durations  $T_R$  ranged between about 100 s and 220 s (Kanamori and Kikuchi, 1993; Hara, 2007b; Lomax and Michelini, 2009a; Bormann and Saul, 2008 and 2009b). This is, according to the relationship  $T_R \approx 0.6M - 2.8$  by Bormann et al. (2009), about 2-4 times longer than expected on average for earthquakes with  $M_w$  around 7.7.

This strongly contrasts with earthquakes  $M_e \gg M_w$ , e.g., for the 12 January 2010  $M_w 7.1$  Haiti earthquake with  $M_e$  values of 7.5 and 7.6, respectively, which caused major devastations and a large number of casualties due to strong ground shaking in conjunction with inferior building stocks. Other examples are given by Di Giacomo et al. (2010a and b). Thus, the difference  $\Delta M = M_e - M_w$  is an important diagnostic aid to quickly assess differences in the kind of seismic hazard and damages to be expected from strong earthquakes.

Another argument in favor of  $M_e$  is that it follows more closely the original intent of the Gutenberg-Richter magnitude formula with  $(A/T)_{\max}$  as the input measurement parameter which relates magnitude to the velocity power spectrum and, thus, to energy. In contrast,  $M_w$  is related to the scalar seismic moment  $M_0$  that is derived from the low-frequency asymptote

of the displacement spectrum. Consequently,  $M_e$  is more closely related to the seismic potential for damage while  $M_w$  is related to the final static displacement and the rupture area and thus related more to the overall tectonic effect of an earthquake.

However, one major advantage of non-saturating  $M_0$  and thus  $M_w$  is that they have to be determined only from very long-period seismic waves with  $T \gg T_c$  (= corner period of the radiated seismic spectrum). This is more easily done and less affected by small-scale complexities in the source process and inhomogeneities along the wave propagation path. Therefore, measurement errors in  $M_w$  are rather low, probably even less than 0.1 m.u. when based on good data.

In contrast, to assure a non-saturating  $M_e$  the squared velocity spectrum would need to be measured widely enough towards both sides of  $f_c$  (respectively  $T_c$ ) in Fig. 3.5 in order to assure that at least some 80% of the total  $E_s$  is obtained from the integration over the source spectrum.  $M_e$  would then be underestimated by less than 0.06 m.u., which is negligible. When assuming that the low frequency part of the source spectrum is completely available, then - according to Singh and Ordaz (1994) - the highest frequency  $f_{\max}$  still to be included should be 6 times  $f_c$  for an  $\omega^{-2}$  model as in Fig. 3.5. However, the frequency range that can in practice be covered within the limits  $f_{\min}$  and  $f_{\max}$  may cut off significant amounts of seismic energy contained both in the low- and the high-frequency part of the source spectrum, especially, if the bandwidth of integration does not cover well frequencies around  $f_c$ . In the latter case  $M_e$  may be underestimated up to a few tenths of magnitude units.

Current routine procedures operate in the period ranges between 0.2 and 100 s (procedure according to Choy and Boatwright, 1995). It is outlined in IS 3.6 and applied at the US Geological Survey (USGS), or 1 and 80 s (automatic near real-time procedure according to Di Giacomo et al., 2010a and b), applied by the GFZ German Research Centre for Geosciences (GFZ). The inclusion of frequencies above 1 Hz is generally difficult because of the then usually low SNR in teleseismic recordings and the difficulties to correct for frequency-dependent attenuation (see Chapter 2, section 2.5.4.2) and local site effects. But then, the condition  $f_{\max} = 6 \times f_c$  for the inclusion of higher frequencies is already difficult to meet for  $M_w < 5.5$  in the case of an average stress drop  $\omega^{-2}$  source model as assumed in Fig. 3.5. And since the average corner periods for magnitude 8.5 earthquakes is expected to be already around 100 s the current procedures will also not be able to sample the spectral amplitudes towards  $T > T_c$ . According to Bormann and Di Giacomo (2011) Eq. (3.72) can be written as

$$M_e = M_w + [\log(\Delta\sigma/2\mu) + 4.7]/1.5. \quad (3.74)$$

This allows to roughly assess the possible influence of variations in stress drop on estimates of  $M_e$ , using the scaling model in Fig. 3.5 but for varying in increments of one order for  $\Delta\sigma$  between 0.1 and 100 MPa (see Tab. 3.3). This range of variations in  $\Delta\sigma$  encompasses most of the published data (e.g., Abercrombie, 1995; Kanamori and Brodsky, 2004; Parolai et al., 2007; Venkataraman and Kanamori, 2004a). The related shift of  $f_c$  for these different  $\Delta\sigma$  values has been plotted in Fig. 3.16 for an earthquake with  $M_w = 6.5$ , and in the inset for a wider magnitude range between  $M_w = 5.5$  and 8.5. According to Fig. 3.16a, variations in  $\Delta\sigma$  do not influence at all the displacement plateau of the source spectrum and thus estimates of  $M_0$  as long as the basic condition of analysing only frequencies  $f \ll f_c$  is observed. In contrast, according to Eq. (3.74) and in agreement with Fig. 3.16b, variations in stress drop by one order are - for a given seismic moment - expected to change the released energy by one

order as well and thus the estimates of  $M_e$  by almost 0.7 m.u.. This complicates matters even more.

In order to sample nearly 100% of the energy radiated by earthquakes with magnitudes between  $5.5 \leq M_w \leq 8.5$  and stress drops between  $0.1 \leq \Delta\sigma \leq 100$  MPa one would need to consider a much wider range of frequencies between 0.001 Hz and 16 Hz instead. This is, however, not realistic, neither with respect to handling the very high-frequency part of the radiated energy nor for fast routine  $M_e$  estimations using teleseismic P-wave records, taking also into account that the longest periods that can be used have to be shorter than the time difference between the onset of the P- and S-wave groups which can not be handled together. For a rough orientation Tab. 3.3 summarizes the magnitude-dependent underestimation of  $M_e$ ,  $-\Delta M_e$ , based on the source model of Fig. 3.5 but assuming variable stress drop between 0.1 and 100 MPa and integration over frequencies between 12.4 mHz and 1 Hz only, as in the GFZ procedure for quick  $M_e$  estimation (see D. Di Giacomo et al., 2010 a and b).

**Tab. 3.3** Estimates of  $-\Delta M_e$  for the GFZ procedure of  $M_e$  determination according to Bormann and Di Giacomo, 2011).

| $\Delta\sigma$ (MPa) | $\Delta M_e$ for $M_w = 5.5$ | $\Delta M_e$ for $M_w = 6.5$ | $\Delta M_e$ for $M_w = 7.5$ | $\Delta M_e$ for $M_w = 8.5$ |
|----------------------|------------------------------|------------------------------|------------------------------|------------------------------|
| 0.1                  | 0.05                         | 0.02                         | 0.05                         | 0.25                         |
| 1                    | 0.13                         | 0.03                         | 0.02                         | 0.10                         |
| 10                   | 0.30                         | 0.08                         | 0.02                         | 0.03                         |
| 100                  | 0.66                         | 0.19                         | 0.05                         | 0.02                         |

According to Tab. 3.3, an  $E_s$  procedure operating in the bandwidth range from 1 to 80 s may underestimate  $M_e$  up to  $\approx 0.66$  m.u. for moderate ( $M_w \approx 5.5$ ) earthquakes with very high stress drop and thus  $f_c > f_{\max}$ . But for most earthquakes with  $M_w$  between about 6.5 and 8.5 and intermediate  $\Delta\sigma$  between about 1 to 10 MPa the underestimation is expected to be  $< 0.1$  m.u. Yet, for great earthquakes ( $M_w > 8$ ) with  $\Delta\sigma < 1$  MPa (possibly  $f_c < f_{\min}$ ),  $-\Delta M_e$  may also reach 0.2-0.3 m.u., or even more for extreme events. However, such estimates with respect to  $M_e$  that are based on so simple a single point source rupture model must be used with caution. No models can account for all real source, propagation path and station site complexities, which luckily do not much affect teleseismic  $M_w$  estimates. Therefore, Tab. 3.3 can only for give a rough orientation of the possible range of  $M_e$  uncertainties.

Underestimations for extreme events should be somewhat reduced by the more elaborate off-line USGS procedure that uses a slightly larger bandwidth and a residual integral for frequencies above  $f_c$  (see Boatwright and Choy, 1986). In summary, according to McGarr and Fletcher (2002),  $E_s$  released by earthquakes can probably be estimated only within a factor of 2-3 if multi-station high-quality seismic broadband data are available. This corresponds to an accuracy within 0.2 to 0.3 m.u. in  $M_e$ . In the same range source directivity may affect related single station  $M_e$  estimates (Venkataraman and Kanamori, 2004b)

Correcting for high-frequency attenuation is one of the most challenging tasks in calculating  $M_e$ . It requires a detailed knowledge of the velocity and attenuation structure along the propagation paths, and also especially below the seismic stations. Available global attenuation models differ still significantly and are controversially discussed and empirical data show significant scatter. Fig. 3.58 compares empirical data of short-period spectral velocity

amplitudes, measured on records of many world-wide distributed broadband stations. The respective spectral amplitude-distance curves have been calculated for two different Earth models, assuming frequency-independent quality factors  $Q$ : a) the AK135Q according to Montagner and Kennett (1996) and b) the Preliminary Earth Reference Model (PREM) according to Dziewonski and Anderson (1981). The inconsistencies for shorter periods are obvious. The usually poor signal-to-noise-ratio at frequencies higher than 1 Hz in the teleseismic range represents another big limitation, especially for moderate and small earthquakes.

**Fig. 3.58** Velocity spectral amplitudes at 0.5 s (2 Hz, light gray triangles), 1 s (1 Hz, black circles) and 2 s (0.5 Hz, gray diamonds) for the  $M_w = 7.9$  Wenchuan, China, earthquake of 2008, May 12, superimposed to the theoretical spectral amplitude decay functions for the same frequencies for the AK135 model (median, 25<sup>th</sup> and 75<sup>th</sup> percentile in solid and dashed red lines, respectively) and the PREM model (median, 25<sup>th</sup> and 75<sup>th</sup> percentile in solid and dashed violet lines, respectively). An arbitrary offset has been added to the theoretical curves to make easier the comparison with the real data. (Courtesy of D. Di Giacomo, 2011).

These combined difficulties and thus - as compared to  $M_0$  and  $M_w$  determinations - related larger possible errors are reasons that  $E_s$  and  $M_e$ , despite their importance in assessing the damage potential of earthquakes, have rarely been used for this purpose so far. This, however, also means that one should not over-interpret differences between  $M_w$  and  $M_e$  less than 0.2 m.u., yet larger ones may already be alarming because they may hint to different kinds of disaster consequences. Since  $M_e$  for the Wenchuan earthquake was almost 0.4 m.u. larger than  $M_w$  (see Fig. 3.59) this may at least partially explain the extra ordinarily large shaking damages. In contrast, the great tsunamigenic Sumatra-Andaman  $M_w = 9.3$  earthquake of 2004 was relatively slow with rupture velocities dropping down from 2.8 km/s at the beginning to 2.1 km/s in the Nicobar rupture segment. Accordingly, the related energy radiation efficiencies (see 3.1.2.5) were only 0.2 to 0.1 as compared to values between some 0.4 to 0.6 for other great earthquakes (Kanamori, 2006). Accordingly, energy magnitude  $M_e(\text{GFZ}) = 8.8$  is 0.5 m.u. units less than  $M_w$  for this earthquake (see Fig. 3.60a) which thus ranks between “normal” great earthquakes and the extremely slow tsunami earthquakes.

**Fig. 3.59** Upper panel: vertical component velocity recording of the  $M_w = 7.9$  12 May 2008 Wenchuan earthquake recorded at the station KMBO (Kenya). The theoretical P-, PP-, PPP- and S-wave arrival times have also been marked. The gray shaded area represents the envelope of high-frequency velocity amplitudes used to constrain the overall rupture time duration (Bormann and Saul, 2008), and the diamond at the end of the black record trace marks the end of the time window after the P-wave onset for which the final  $M_E$ (GFZ) single station value is calculated. Thus, the full rupture duration is included in the  $E_S$  calculation. However, the rupture duration may last for several minutes (as for the great 26 December 2004 Sumatra earthquake). Then the entire S-P window should be considered. Lower panel:  $E_S$  (left y-axis) and  $M_E$  (right y-axis) values for different cumulative P-wave windows. The diamond marks the end of the P-wave window that has been used for the single station  $M_E$  estimate. (Courtesy of D. Di Giacomo, 2011).

To evaluate the amount of time needed by this procedure to provide a stable  $M_E$  in a real- or near-real time implementation, Fig. 3.60 shows the  $M_E$  determinations at different times after OT for both the great 26 December 2004 Sumatra earthquake (Fig. 3.60a) and the 12 May 2008 Wenchuan earthquake (Fig. 3.60b). In the exceptional case of the 2004 Sumatra earthquake, for which the rupture duration as estimated from the duration of the P-wave train was about 500 s (Bormann and Wylegalla, 2005; Ni et al., 2005), this procedure could have yielded a stable  $M_E$  already some 15 min after OT (Fig. 3.60a, right panel), since the major energy release occurred within the first 250 s of the rupture process (Choy and Boatwright, 2007). For the case of the Wenchuan earthquake, instead, using P-wave time windows of 180 s, more stations (24) could have been used already 10 min after OT, and a stable  $M_E$  could have been released. Noticeably, in both cases the preliminary (alarm)  $M_E$ (GFZ) available after 10 min are very close to the final values obtained by using all available stations. Of course, the time performance of this approach depends on the station availability with respect to the earthquake location. However, the worldwide station deployment is becoming increasingly dense, especially in areas for which a lack of instrumentation was still common a few years ago. Therefore, this procedure could yield in the near future rapid  $M_E$  estimates within 10 min after OT also for great ( $M_w \geq 8$ ) earthquakes.

**Fig. 3.60** **a) Left:** Map showing the location of the 26 December 2004 Mw = 9.3 Sumatra earthquake (red star), the broadband stations used to calculate  $M_E(\text{GFZ})$  (black triangles), and the red circles represent the S-wave arrival after OT. **Right:**  $M_E(\text{GFZ})$  determination of the Sumatra earthquake at different time after OT. The number of stations used to compute  $M_E(\text{GFZ})$  are also given; **b) As for a)** but for the 12 May 2008 Mw = 7.9 Wenchuan earthquake. Here the red circles on the map mark the time needed to record 180 s of P-waves.

### 3.2.8 Complementary non-saturating magnitude scales (P. Bormann)

#### 3.2.8.1 Cumulative body-wave magnitude mBc

In their fundamental paper about energy and magnitude of earthquakes Gutenberg and Richter (1956a) shortly explain that their mB-log $E_S$  relationship is based on the assumption of a point source which radiates a simple-shaped waveform whose largest amplitude and duration are related to each other. This makes it possible to estimate the seismic energy travelling with this waveform by scaling it to  $A_{\max}$ , respectively  $(A/T)_{\max}$ . They also mention that because of lacking data for stronger and likely more complex earthquakes the mB-log $E_S$  relationship, which in fact is based on only 20 data points in the magnitude range between  $5.3 \leq m \leq 8$  and one data point for  $m = 2$  (see Fig. 3.83), may be less reliable. Indeed, larger earthquakes tend to be multiple source ruptures (see Figs. 3.9-3.13). Single-amplitude mB is then representative only for the largest sub-rupture. This let Bormann and Khalturin (1975) propose:

*“In such cases we should determine the onset times and magnitudes of **all clear successive P-wave onsets separately**, as they give a first rough impression of the temporal and energetic development of the complex rupture process.” And further: „The magnitude  $MP = \log \Sigma n (A_i / T_i) + Q(D, h)$  ( $n$  is the number of successive P-wave onsets) could be considered as a more realistic measure of the P-wave energy released by such a multiple seismic event [...].“*

Bormann and Wylegalla (2005) demonstrated this by way of example for the great 2004 Mw9.3 Sumatra-Andaman earthquake. Just a single broadband station record near Berlin yielded a cumulative  $\Sigma mB$ , now termed mBc, of 9.4 and a rupture duration estimate of about 500 s. Meanwhile, this procedure has been fully automated (see Figs. 3.13 and 3.62, and for details Bormann and Saul, 2009b). Fig. 3.61 left shows the data and orthogonal regression relation (3.75) of Harvard CMT Mw(HRV) vs. mBc. Using Eq. (3.75) mBc can be converted into a proxy estimate of moment magnitude,  $Mw(mBc) = Mw^*$ . Fig. 3.61 right compares  $Mw^*$  with proper Mw(HRV). With  $SD_{OR}$  = orthogonal standard deviation and  $SD_Y$  in y direction holds:

$$Mw(HRV) = 1.22 \text{ mBc} - 2.11 \text{ with } SD_{OR} = 0.145 \text{ and } SD_Y = 0.23 \quad (3.75)$$

**Fig. 3.61 Left:** Orthogonal regression Mw(HRV) over mBc with 1-SD and 2-SD limits in dark and light grey; **red dots - tsunami earthquakes, blue dots – deep earthquakes**; **Right:** proxy  $Mw^* = Mw(mBc)$  calculated via Eq. (3.75); **black dots – tsunami earthquakes**. Data according to Bormann and Saul (2009); Figure kindly provided by J. Saul, 2009.

Thus, equation (3.75) allows to compute a purely empirical  $Mw^*$  estimator  $Mw(mBc)$ , which is sufficiently accurate and quick to be used as a preliminary proxy Mw in tsunami early warning applications until Mw(HRV) (now Mw(GCMT)) becomes available. Most events follow the two regressions well. For 80 percent of the events,  $|Mw^* - Mw| < 0.25$  m.u. For only two events  $Mw^*$  is significantly too low. They correspond to the very slow Mw 7.6 1992 Nicaragua and the Mw 7.8 1994 Java tsunami earthquakes. Yet, for two more tsunami earthquakes in our data set ( $M_w$  7.5 Peru 1996;  $M_w$  7.7 Java 2006, see Fig. 3.62)  $Mw^*$  agrees within less than 0.25 m.u. with Mw, also for other major tsunamigenic events like the great 2004 and 2005 Sumatra earthquakes.

**Fig. 3.62** Velocity-proportional broadband record of the Mw 7.7 July 2006 Java tsunami earthquake at station II.PALK processed with the automated mBc procedure by Bormann and Saul (2009b). Blue bars correspond to mB values of major amplitude onsets according to the condition  $V_i \geq 0.6V_{\max,t}$  with  $V_{\max,t}$  being the maximum velocity amplitude up to the time  $t$ . The largest sub-event single-amplitude mB = 7.0 has been marked by a blue triangle. The red curve shows the development of mBc with time and the red triangle the asymptotically saturated mBc value reached prior to the onset of S. The grey shaded area marks the high-frequency (HF) P-wave envelop. The apparent rupture duration  $d_{app}$  is measured from the P-onset up to the red triangle where the HF envelope amplitudes have dropped to 40% of their maximum value, corresponding to 16% energy wise.

From Fig. 3.61 left one realizes that mBc tends to overestimate increasingly magnitudes for  $M_w < 8$ . This means that for smaller earthquakes Gutenberg and Richter's (1956a) original assumptions of a simple scaling of the maximum far-field P-wave amplitude to the duration of the waveform and its related seismic energy holds on average sufficiently well. Accordingly, summing up multiple P-wave onsets for smaller earthquakes tends to yield  $mBc > M_w$  and  $> mB$ . The apparent rupture duration estimates published by Bormann and Saul (2008 and 2009) agree for 90% of the investigate earthquakes within 10% with those published by Lomax and Michelini (2009a) for the same events, yet with a tendency of mB-mBc durations to be deliberately somewhat longer. This was necessary for assuring that the depth phases of P are included within this time window in order to satisfy IASPEI rules for mB measurements (see explanations to formulas (3.44 and 3.45). For the Java tsunami earthquake in Fig. 3.62  $d_{app} = 190$  s, which is almost three times longer than the rupture duration of 66 s estimated with formula (3.3) for an "average"  $M_w = 7.7$  earthquake.

### 3.2.8.2 Mwp

A simple, fast and robust method of  $M_w$  determination from broadband P waveforms, termed Mwp, has originally been developed by Tsuboi et al. (1995) for quick estimation of the moment magnitude  $M_w$  and the tsunami potential of large near coastal earthquakes offshore of Japan. It has later been extended by Tsuboi et al. (1999) for application also to teleseismic earthquakes in general. Since then Mwp has become the main procedure at the Pacific Tsunami Warning Center (PTWC) for rapid rough  $M_w$  estimation. The procedure is based on the double integration of broadband P-wave velocity records and scaling of the maximum of the resulting source-time function via  $M_0$  to  $M_w$  (Fig. 3.63).

**Fig. 3.63** **Black trace:** Original velocity-proportional vertical component P-wave record; **Blue trace:** Twice integrated record trace. According to Seidl and Berckhemer (1982) the **area** underneath the blue trace is proportional to  $M_0$ . For simplicity Tsuboi et al. (1995) scaled the first maximum of the blue trace to  $M_{wp}$ .

However, the original scaling as well as later introduced corrections were not so straightforward. Scaling to the first peak in the double integrated trace which is in fact the far-field source-time function, and not to the area underneath the total source-time function (see also Fig. 3.65a), assumes a single point source rupture model with a more or less symmetric moment-rate function and a simple relationship between the maximum amplitude and the area underneath the curve. Later, Tsuboi et al. (1999) changed this by scaling  $M_{wp}$  to the largest of the first two maxima, accepting that this could relate either to a stronger depth phase (pP or sP) or to a stronger sub-event of the progressing rupture. Yet still, in the case of very large, more complex or very slow ruptures,  $M_{wp}$  tends to underestimate the true  $M_w$ , because even later sub-ruptures than the second one may have the largest amplitude, and most importantly, the rupture duration is not taken into account. For equal maximum amplitude of the source time function its duration and thus the area underneath the function may vary strongly, being much larger, e.g., in the case of slow earthquakes. Even with magnitude-dependent corrections introduced the  $M_{wp} = 8.2$  for the great 2004 Sumatra earthquake turned out to be much too small (see Hirshorn and Weinstein, 2009). This value was later increased to  $M_{wp} = 8.5$  by assuming a variable apparent P-wave velocity (Kanjo et al., 2006).

Accordingly,  $M_{wp}$  turned out to be neither more efficient nor faster than the simple automated direct measurement of the traditional Gutenberg  $m_B$  on velocity broadband records, which is now a new IASPEI body-wave standard. The reason is that also  $m_B$  is based on the same simplified assumption, namely that the maximum amplitude of a single point source waveform in the far-field is scaled to the area underneath this waveform.

When plotting  $M_{wp}$  over  $m_B$  (see section 3.2.8.1)) one gets almost a 1:1 orthogonal regression relationships whereas  $m_{Bc}$  is always larger but not saturating as do both the single amplitude  $m_B$  and  $M_{wp}$  (Fig. 3.64). The regression relations are:

$$M_{wp} = 1.06 mB - 0.09$$

and

$$M_{wp} = 0.95 mBc - 0.47.$$

**Fig. 3.64** Data and orthogonal regression relationships between  $M_{wp}$  of the Pacific Tsunami Warning Center and  $mB$  (left), respectively  $mBc$  (right), according to data of Bormann and Saul (2009). Figure courtesy of J. Saul, 2009.

### 3.2.8.3 $M_{ED}$ and $M_{wpd}$

The main drawback of both  $M_{wp}$  and  $mB$  (in contrast to  $mBc$ ) is that rupture duration and related major sub-events in seismic energy and moment release are not taken into account. The lack of these contributions, which may become very significant for great multi-source or extremely long-lasting ruptures (see Fig. 3.65a below), results in the underestimation of the overall event magnitude and thus of the tsunamigenic potential of really great earthquakes and of slow tsunami earthquakes in particular (e.g., Fig. 3.74 in section 3.2.9.4 and Hirshhorn and Weinstein, 2009).

To address this problem, and for rapid and accurate determination of the size and tsunamigenic potential of strong and great earthquakes, Lomax et al. (2007) and Lomax and Michelini (2009a) developed non-saturating, energy,  $M_{ED}$ , and moment,  $M_{wpd}$ , magnitudes, which explicitly take into account rupture duration. Similar to the procedures by Bormann and Saul (2008 and 2009) for measuring  $mB$  and  $mBc$  on velocity broadband records, the  $M_{ED}$  and  $M_{wpd}$  procedures estimate the apparent rupture duration,  $T_0$ , on high-frequency (HF; 1-5 Hz) filtered vertical component broadband seismograms.  $M_{ED}$  is based on an energy-duration procedure which cumulated energy in the time interval  $t_{T_0} - t_p$  on vertical component, broadband velocity seismograms. The developed relationship between the estimated released seismic energy and the measured apparent rupture duration allowed a rapid estimation of  $\Theta = \log(E_S/M_0)$  for identifying slow but dangerous tsunami earthquakes, namely, if  $\Theta$  drops below -5.7.

Mw<sub>pd</sub> is based on a duration-amplitude procedure which is equivalent to cumulative application of the Mw<sub>p</sub> algorithm (i.e., moment determination) in the time interval  $t_{T0} - t_p$  on vertical component, broadband displacement seismograms. In operational application Mw<sub>pd</sub> values can be made available within about 10 min after origin time (OT) (Fig. 3.65a). First results showed, however, that additionally a scaling of the moment estimates was necessary in order to assure a better match with Mw(CMT). With such a scaling the difference  $|Mw_{pd} - Mw(CMT)|$  for events with magnitude  $6.6 \leq Mw \leq 9.3$  was typically within  $\pm 0.2$  m.u., with a standard deviation  $SD = 0.11$  m.u. This moment correction has recently been simplified, along with other modifications, to enable faster, more robust real-time estimates of Mw<sub>pd</sub> (Lomax and Michelini, 2012).

Lomax and Michelini (2009b, 2011) show that neither  $\Theta$  nor Mw alone proved to be good indicators for tsunamigenic earthquakes in general, while apparent rupture durations longer than about 50 s combined with predominant P-wave period  $T_p$  greater than about 10 s are good indicators. Lomax and Michelini (2009b) also show that measures on 1-5Hz HF filtered velocity broadband records alone can show for most earthquakes within 4-6 min after OT if the rupture duration is likely to exceed 50 s, indicative for tsunamigenic and tsunami earthquakes. Although less accurate than  $T_0$ , this rapidly available measure,  $T_{50EX}$ , is an important complement in operational tsunami early warning schemes. By combining  $T_{50EX}$  with a measurement of the predominant period,  $T_d$ , in the early part of the P-wave record, and later by estimating the apparent total rupture duration  $T_0$ , the products  $T_d T_{50EX}$  and  $T_d T_0$  can be calculated (see Fig. 3.65b). These products proved to be reliable indicators for the tsunamigenic potential of earthquakes in general and for slow tsunami earthquakes in particular, superior to Mw(GCMT) (Lomax and Michelini, 2011, 2012). The reason is that the efficiency of tsunami generation by a shallow earthquake depends on the amount of sea floor displacement, which can be related to a finite-faulting model expressed by the *seismic potency*,  $LWD$ , where  $L$  is the length,  $W$  the width, and  $D$  the mean slip of the earthquake rupture (Kanamori 1972; Abe 1973; Polet and Kanamori, 2009). Mw is calculated from the seismic moment  $M_0 = \mu LWD$  by assuming that  $\mu$ , the shear modulus at the source, and thus also  $LWD = M_0/\mu$  are constant and independent on source depth. This, however, is not the case, especially in shallow subduction zones.  $\mu$  may there strongly decrease with source depth and fault rupture may occur close to the sea bottom on non-planar, lystric splay faults in water saturated sediments in the accretionary wedge (Fukao, 1979; Moore et al., 2007; Lay and Bilek, 2007). This will result in strongly reduced rupture velocity and stress drop and thus longer rupture duration with longer dominating periods of the radiated P-waves. In general, CMT algorithms, do not account for this low velocity and shear modulus. Accordingly, the seismic potency and tsunami potential may be underestimated, especially in the case of unusually slow “tsunami earthquakes”, which, by definition, cause larger tsunami waves than one would expect from their Mw (Kanamori, 1972; Satake, 2002; Polet and Kanamori, 2009; Newman et al., 2011). Both  $T_d$  and  $T_0$ , as well as the estimator of critical duration,  $T_{50EX}$ , “sense” these differences in source-depth dependent  $\mu$ , and related reduced rupture velocity, increased rupture duration and potency  $LWD$ , and consequently increased sea surface displacement and tsunami potential.

The Mw<sub>pd</sub> and TdT<sub>50EX</sub>-Td T<sub>0</sub> procedures have been implemented operationally at the Istituto Nazionale di Geofisica e Vulcanologia (INGV) in Rome, Italy.

#### 3.2.8.4 Hara's maximum amplitude-duration magnitude M

In a slightly different and very straight forward empirical procedure, Hara (2007a and b) combines measuring the high-frequency duration of the P-wave train with just the maximum P-wave displacement amplitude in broadband records to determine an empirical relation for a non-saturating magnitude M scaled to Mw in the Harvard CMT catalog:

$$M = 0.79 \log A + 0.83 \log \Delta + 0.69 \log t + 6.47$$

where A is the maximum displacement (in m) during the estimated duration t (in s) of high-frequency energy radiation since the P-wave first arrival time and  $\Delta$  the epicentral distance (in km).

The Hara M matches with Mw(CMT) typically within  $\pm 0.3$  m.u., with SD = 0.18. It is also applicable to tsunami earthquakes (2007b) that are characterized by relatively longer rupture duration but smaller amplitudes. However, in this case M underestimates, as Mw, the tsunami magnitude  $M_t$  (see 3.2.6.7).

#### 3.2.8.5 Mantle magnitude Mm

Another important teleseismic magnitude is called mantle magnitude Mm. It uses surface waves with periods between about 60 s and 410 s that penetrate into the Earth's mantle (see section 2.3.4 in Chapter 2). The concept has been introduced by Brune and Engen (1969) and further developed by Okal and Talandier (1989 and 1990). Mm is firmly related to the seismic moment  $M_0$  and thus avoids saturation. On the other hand, it is closer to the original philosophy of a magnitude scale by allowing quick, even one-station automated measurements (Hyvernaud et al., 1993), that do not require the knowledge of either the earthquake's focal geometry or its exact depth. The latter parameters would be crucial for refining a moment estimate and require (global) network recordings.

Mm is an estimate of  $(\log M_0 - 13)$  (when  $M_0$  is given in Nm) and defined as:

$$Mm = \log X(\omega) + C_S + C_D - 0.90$$

where  $X(\omega)$  is the spectral amplitude of a Rayleigh wave in  $\mu m-s$ ,  $C_S$  a source correction, and  $C_D$  a frequency-dependent distance correction. For details of the correction terms, see Okal and Talandier (1989 and 1990).

Best results are achieved for  $Mw > 6$  at distances  $> 15-20^\circ$  although the Mm procedure has been tested down to distances of  $1.5^\circ$  (Talandier and Okal, 1992). However, at  $D < 3^\circ$  the seismic sensors may be saturated in the case of big events. Also, at short distances one may not record the very long periods required for saturation-free magnitude estimates of very strong earthquakes, and for  $Mw < 6$  the needed very long-period records may become too noisy. A signal-to-noise ratio larger than 3.0 is recommended for reliable magnitude estimates.

Mm determinations have been automated at the Pacific Tsunami Warning Center (PTWC) and the Centre Polynésien de Prévention des Tsunamis (CPPT) (Weinstein and Okal, 2005; Hyvernaud et al., 1993) so that values are available in near real-time within about 10 min after OT from near stations, however typically within about half an hour, plus a few minutes more for really great earthquakes measured at the longest periods. Mm does not – or only marginally – saturate, even for very great, slow or complex earthquakes.

Applications of Mm to the reassessment of the moment of shallow, intermediate and deep historical earthquakes are extensively described by Okal (1992 a and b). For the Chile 1960 earthquake Okal (1992a) calculated values  $M_m \approx 10$  to  $10.3$  and for  $M_0 = 3.2 \cdot 10^{23}$  Nm. Mm determinations were extensively verified and are said to be accurate by about  $\pm 0.2$  magnitude units (Hyvernaud et al., 1993).

### **3.2.8.6 W phase rapid Mw estimates and moment tensor solutions**

In section 2.6.6 of Chapter 2 the nature and appearance of the very long-period W phase between the P and S-wave onsets have been shortly described (see Figs. 2.74 and 2.75). The inversion of the W phase for sufficiently strong earthquakes by optimizing the fit between W phase synthetics to empirical records (see Fig. 3.66) yields rather rapid (within about 25 minutes after the earthquake occurrence) and reliable first seismic moment tensor solutions and thus of both Mw (within about 0.1 m.u.) and the source mechanism of strong earthquakes (see Fig. 3.67). Therefore, such applications have recently gained immense practical importance for speeding up seismic tsunami warning, as proposed by Kanamori and Rivera (2008). First real-time implementations are operational at the U.S. Geological Survey's NEIC (Hayes et al., 2009) as well as at the GFZ Potsdam and the Indonesian Tsunami Early Warning System (InaTEWS) since 2011.

**Fig. 3.67** Examples of operationally derived source parameters from W phase inversion in comparison to global Centroid Moment Tensor (gCMT) solutions. Solutions derived from station records at up to 50° epicentral distance were on average available 24 min after OT and those from stations up to 90° epicenter distance within about 48 min. Optimized denser grid search takes more time with no significant difference. Copy of Figure 3 of Hayes et al. (2009), Seismological Research Letters, Vol. 80, No. 5, page 821; © Seismological Society of America.

### 3.2.9 Relationships among different magnitude scales

(P. Bormann, D. Di Giacomo and S. Wendt)

#### 3.2.9.1 Remarks about regression and correlation relationships (P. Bormann)

Most of the published classical relationships between different types of magnitudes are simple linear standard regressions of type one (SR1), also termed ordinary least-square (OLS) regression. But often authors have not even specified in an unambiguous way the type of regression or data correlations they have applied. Yet, least-square fits may be done in very different ways. Sometimes, even eye-fits are not the worst, because they intuitively accept that the data scatter relates to both compared variables. The approximate relationship (3.3) is such a best eye-fit through a largely scattering data cloud yielding a very simple and sufficiently reliable formula in the context of the great variability of individual data points. Also the famous Gutenberg-Richter relationship between  $\log E_s$  and  $m$  (respectively  $m_B$ ) shown in Fig. 3.83 is obviously just an eye-fit but never stated explicitly as such. Moreover, some relationships, such as the  $\log E_s$ - $M_s$  relationship by Choy and Boatwright (1995), are just a least-square fit with respect to a prescribed slope, namely to the slope of 1.5 in the famous Richter (1958)  $\log E_s$ - $M_s$  relationship. The reason was to assure compatibility of the new relationships with already since long widely used and well established relationships, at least with respect to some essential parameters such as the slope or general trend. Yet, proper linear regression through the same data set would yield both another slope and another constant (see section 3.3.3).

Standard regressions are least-square fits through the data cloud, which consider the scatter in plots of the  $(x_i, y_i)$  data pairs as being related solely to the dependent ordinate variable  $Y$  while assuming that the errors of the “independent” (or given) abscissa variable  $X$  are zero or negligibly small. In contrast, the inverse standard regression ISR (or standard regression SR2), is based on the opposite assumption that only  $X$  is afflicted with initial errors, but not  $Y$ . Accordingly, the slopes of SR1 and SR2 will differ, the more the larger the scatter of the data points and the smaller their correlation co-efficient.

Since generally all types of measured/calculated magnitude values are afflicted with initial errors, such standard regression relationships are not optimal. They can only be used in the way they have been derived, i.e., for converting a given magnitude, assumed to be error free, into another one by estimating its average value and related uncertainty, such as its standard deviation. In fact, a standard regression projects the actual errors in the given variable into an increased error of the estimated dependent variable. Therefore, resolving an SR1 relationship  $Y$  over  $X$  for the variable  $X$ , as sometimes practiced when converting magnitudes, is not correct. Such a misuse of standard regressions easily results in conversion errors of 0.2 – 0.3 magnitude units (Gutdeutsch et al., 2011) but may become, in the case of rather noisy, especially short-period magnitude data, as large as about 1 m.u. in some magnitude ranges [e.g. in Fig. 3.68 left and conclusion drawn from comparing Eq. (3.78a) and (3.78d)], unless the initial errors of both variables are rather small and the correlation coefficient is close to 1 so that the difference in slope between SR1 and SR2 in the same  $X$ - $Y$  plot becomes negligible (see Fig. 3.68 right).

**Fig. 3.68** Standard regressions SR1 of vertical component PP-wave magnitudes over vertical component P-wave magnitudes, measured on either short-period records of type A (left) or broadband records of type B (right), which correspond to type A4 and C, respectively, in Fig. 3.20 left). SR1 is compared with the respective inverse standard regression SR2 of MPV over MPPV and the common orthogonal standard regression OSR, written in the form Y over X (see thick solid line between SR1 and SR2). Note the different slopes of SR1 and SR2, depending on the data scatter, which is much less for the broadband versions of MPV and MPPV.  $S_{\perp}$  = orthogonal standard deviation. From Figures 3 and 4 in Bormann and Khalturin (1975).

The simplest way to mitigate this problem is to calculate orthogonal standard regressions, OSR, assuming that both variables are afflicted with initial errors of about the same size (ideally with an error ratio 1). This has been practiced, e.g., by Bormann and Khalturin (1975), Bormann and Wylegalla (1975), Ambraseys (1990), Gusev (1991), Gutdeutsch et al. (2002), Grünthal and Wahlström (2003), Bormann et al. (2007 and 2009), Ristau (2009) and Das et al. (2011). In the two papers by Bormann et al. (2007 and 2009), the OSR solutions are deliberately presented together with SR1 and SR2 in order to see the differences and their dependence on the correlation coefficient (e.g., Figs. 3.49 and 3.50). In another publication, Castellaro and Bormann (2009) could show, that as long as the true error ratio, or the square root of the true variance ratio  $\eta_{\text{true}}$ , of the two variables ranges between  $0.7 < \sqrt{\eta_{\text{tru}}} < 1.8$  the orthogonal standard regression under the assumption of  $\eta = 1$  is still superior to SR1 or SR2. This condition is usually fulfilled when comparing magnitudes that have been measured at comparable periods. But outside of this error ratio range, either SR1 or ISR = SR2 represent the data relationship better, depending also on how much their slope deviates from 1.

In reality, however,  $\sqrt{\eta}$  may become as small as about 0.3, e.g. when comparing short-period mb with typical initial errors in the range between 0.2 and 0.3 (see also Table 5 in IS 3.3), with Mw(GCMT), for which initial errors are assumed to be not larger, often even less than 0.1 m.u. (personal communication by G. Ekström, 2009; see also Helfrich, 1997; Kagan, 2003 and 2003; Gasperini et al., 2012 and 2013a). Gasperini et al. (2013b) assumed, e.g., for mb determinations an average initial error of 0.25 m.u. and for Mw of 0.1 m.u., corresponding to  $\sqrt{\eta} = 0.4$  or  $\eta = 0.16$ .

Regrettably, in most classical papers the initial measurement errors of used event magnitudes are not given, probably not even known, also because the data reports, catalogs or bulletins of the de facto seismological World Data Centers such as the USGS-NEIC, the Global Centroid Moment Tensor (GCMT) project, or the International Seismological Centre (ISC) did not provide consistently such information. This problem is expected to disappear at the ISC thanks to the implementation of the new ISC locator (Bondár and Storchak, 2011) which computes  $M_s$  and  $m_b$  with uncertainties. Therefore, usually one could only estimate the approximate error ratio by own investigations. These may, however, yield different average measurement errors (standard deviations) even for equal types of magnitudes, depending on differences in instrument calibration, record reading accuracy, aperture and station site distribution of the network, regional variability of station site effects due to variable topographic and geologic conditions, etc. Table 5 in IS 3.3 compares such estimates for single expert readings of event magnitudes from records of the German Regional Seismic Network with those of an analyst team at the China Earthquake Network Center (CENC) based on records of the much larger China National Seismic Network.

If  $\sqrt{\eta}$  differs from 1 and one knows sufficiently well this average error ratio, then a general orthogonal regression (GOR) (for procedures see Fuller, 1987; Castellaro et al., 2006; Das et al., 2011; Lolli and Gasperini, 2012) would be closer to optimal than OSR. Yet, there has been another approach in this direction by Stromeier et al. (2004; see also Appendix 2 in Gasperini et al., 2013b), applying a Chi-squared regression for seismic strengths parameter relations. The *Chi-square* method is based on the theory of independent and normally distributed errors and provides a mathematical explanation for the results derived by Castellaro and Bormann (2009). Gutdeutsch et al. (2011) could show, that the results of these two different approaches agree well as long as the mean initial errors are  $< 0.5$  m.u. Also Lolli and Gasperini (2012) investigated in detail the performance of GOR, the Chi-squared regression and the weighted total least squares approach (Krystek and Anton, 2007). Although the formulations of these three approaches appear quite different, the authors showed that, under appropriate conditions, all compute almost exactly the same regression coefficients and very similar formal uncertainties. Thus, the availability of more general and theoretically correct tools for performing regression analysis and deriving conversion relationships between different types of magnitudes demonstrates the importance of knowing and taking into account their true average initial errors. Regrettably, these were commonly unknown so far. Therefore it would be highly desirable to complement current data parameter calculations and documentation at the most relevant seismological data centers accordingly. And in all publications about regression and conversion relationships the specifics of the applied procedure and its compatibility or incompatibility with other approaches should be unambiguously outlined and documented.

One should also be aware, that GOR procedures developed, proposed or applied by different authors may differ significantly. E.g., a modified GOR methodology proposed by Das et al. (2012) and Wason et al. (2012) and applied by Das et al. (2013) for converting  $m_b$  into  $M_w$  values for regional data from Japan, Mexico, the Indian Himalaya region and the Peninsula Indian region claims to reduce significantly both the average absolute difference as well as the standard deviation between the  $M_w$  proxy estimates and observed  $M_w$ (GCMT). Moreover, it is said to be less dependent on the usually not well known initial error ratio  $\eta$ . However, Gasperini and Lolli (2013) argue that the new method is based on some incorrect assumptions, in particular the use as goodness-of-fit criterion of the simple standard deviation (or of the absolute difference) between computed and observed  $M_w$  which would limit the suitability of such methodology and of the regression relations derived therefrom.

Yet, the issue is even more complicated because of the “saturation” tendency of several magnitude scales (see Fig. 3.47). Saturation is the larger the more narrowband the records are on which the amplitudes and related periods are measured and the more the seismographs peak-response frequencies are shorter than the source corner-frequencies. Therefore, linear regression relations have only a limited value when comparing strongly saturating magnitudes (e.g., short-period mb or ML) with long-period Ms or Mw. Then only stepwise linear fits in limited magnitude ranges may yield still reasonable conversion relationships with not to large conversion errors (e.g., Fig. 3.69), or non-linear regression relationships as in Figs. 3.70a and b, 3.81-82 and 3.91-92. Moreover, short-period magnitudes are generally afflicted with larger errors (see Fig. 3.68) due to the larger influence of local site effects and small-scale heterogeneities along the propagation paths. But the larger the measurement errors of the independent (given; to be converted) magnitude are with respect to those of the dependent (to be estimated) magnitude the greater is the need to avoid standard least-square or orthogonal standard regression, linear or non-linear, but to use GOR or Chi-squared regressions instead with reasonable estimates of the error ratio (see Fig. 3.70b). One cannot regress correctly a pronounced non-linear magnitude relationship without accounting for the difference in the measurement errors, which is usually associated with this non-linearity.

**Fig. 3.69** Step-wise OR regression between vertical-component short-period mb (in a wide measurement time-window up to 1 min) and MLV(C) (of Ms\_BB type) based on magnitude determinations at station MOX, Germany, for global earthquakes. Amended Fig. 5 of Bormann and Khalturin (1975). When extrapolating the uppermost right OR relationship in Fig. 3.69 for  $6.0 < \text{MLV} \leq 8.3$  up to the  $\text{MLV} = \text{Ms\_BB} = 8.9$  measured for the great Sumatra-Andaman Mw9.3 earthquake, one would “predict” an  $\text{mb} = \text{MPV} = 7.3$ , which agrees within 0.1 m.u. with the actual observation.

Non-linear “maximum-likelihood” regressions have been systematically applied for the first time by Gusev (1991) by investigating the relationships between Mw and the magnitudes mb (with  $A_{\text{max}}$  measured within first few seconds only), mSKM (with  $A_{\text{max}}$  measured in the whole P-wave group), mB,  $m_b^*$  (according to Koyama and Zheng, 1985),  $\hat{m}_b$  (according to Houston and Kanamori, 1986), ML, Ms, and M(JMA) in both graphic and tabular form. Some of these

relations are presented in Figure 9 of IS 3.7 in this Manual with respect to  $M_w$  and the Russian  $K = \log E_s$  class system of earthquake classification.

Another form of non-linear average eye-fit relationships of classical magnitudes with respect to  $M_w$  as a reference have also been derived by Utsu (2002) (see Fig. 3.70a), who also discusses extensively the specifics of the types of magnitudes and data, on which these relationships are based.

**Fig. 3.70a** Average non-linear relationships between different common types of magnitudes and the moment magnitude  $M_w$ . (Modified from Figure 1 in Utsu (2002): Relationship between magnitude scales. In: Lee W. H. K., Kanamori, H., Jennings, P. C., Kisslinger, C. (Eds) *Earthquake and Engineering Seismology*, Vol. A, 733-746; © Academic Press, London).

In conjunction with the elaboration of the ISC-GEM Global Instrumental Earthquake Catalogue (1900-2009) (see [www.isc.ac.uk/iscgem/citing.php](http://www.isc.ac.uk/iscgem/citing.php)) new empirical relationships were derived by using both linear GOR and exponential non-linear ordinary least-square (OLS) models to obtain  $M_w$  proxies from  $M_s$  and  $m_b$  (Di Giacomo et al., 2013; see Figs. 3.81 and 3.82). The new models were **tested against true values of  $M_w$ (GCMT)**, and the newly derived exponential models were found to be preferable to the linear ones (see section 3.2.9.5 for the data and comparison with GOR regression). Instead of the bi- or tri-linear regression (as in Fig. 3.69), the two data sets were fit with single, continuous regression curves using an exponential model of the form  $M_y = e^{(a+b \times M_x)} + c$ . The regression was performed using the non-linear least square algorithm by Bates and Watts (1988) and Bates and Chambers (1992), which is freely available with the R-language (<http://www.r-project.org/> or <http://stat.ethz.ch/R-manual/R-patched/library/stats/html/nls.html>).

However, Gasperini et al. (2013b) point out that also exponential models, based on OLS fits, i.e., assuming that only the ordinate variable (in this case  $M_w$ ), are not optimal. Moreover, with respect to  $m_b$ - $M_w$  conversion relationships, one has to consider that global centroid moment tensor solutions (GCMT) tend to be incomplete at values below  $M_w(\text{GCMT}) = 5.5$ , but  $m_b(\text{ISC})$  only at about one magnitude unit smaller values. Gasperini

et al. (2013b) suspect therefore that this early truncation or incompleteness of  $M_w$  values results in a biased, too much bended trend relationship with too small slope of  $M_w$  over  $m_b$  towards smaller magnitudes. Moreover, they argue that this bias is particularly strong developed when applying the OLS exponential fit instead of a Chi-squared (CSQ) fit that assumes a realistic error ratio between  $M_w$  and  $m_b$ . Their CSQ fit yields for  $m_b < 4.5-5$  a nearly 1:1 relationship between  $m_b$  and  $M_w$  (see Fig. 3.70b). This is in better agreement with Fig. 3.70a, the relation of  $m_b$  and  $M_l$  with smaller regional  $M_w$  values (see Tab. 3.6 with comment on the  $M_l$ - $M_w$  relationships, Fig. 3.70b for  $M_w$ (MED) data and the related Figure 2 in Gasperini et al., 2013b). A nearly 1:1  $m_b$ - $M_w$  relationship is also supported by theory. According to Fig. 3.5 it is likely that magnitudes based on  $A_{\max}$  measured at frequencies larger than about 0.3 Hz sample spectral plateau amplitudes required for  $M_0$  and thus  $M_w$  determination and therefore do no longer systematically underestimate  $M_w$ .

Fig. 3.70b illustrates the above discussion. Different exponential regression relationships have been applied to an integrated global  $M_w$  data set (GBL) compiled according to Gasperini et al. (2012) and the related  $m_b$  estimates provided by the ISC on-line bulletin. For data sources see Appendix A in Gasperini et al. (2013b). The figure reveals, how different also non-linear regression relations may be when they are based on very different assumptions about the error ratio of the two variables. Note that also the exponential inverse least square (ILS) curve has been plotted. It is even closer to the CSQ fit than the OLS curve (see discussion below). Formulas for the exponential Chi-square regression model are given in Appendix 2 of Gasperini et al. (2013b).

**Fig. 3.70b** Comparison of different exponential (EXP) fits through the Gasperini et al. (2012) global (GBL)  $M_w$  dataset and the related ISC  $m_b$  data. For the Chi-square (CSQ) regression an error ratio  $M_w/m_b$  of 0.4 has been assumed. OLS and ILS stand for the ordinary (SR1) and the inverse (SR2) least-square regressions and MED for a regional (Mediterranean)  $M_w$ - $m_b$  data set down to  $M_w$  3.5 as plotted in Figure 2 by Gasperini et al. (2013b). Figure provided by courtesy of P. Gasparoni and B. Lolli.

Most strikingly in Fig. 3.70b are: a) the large difference between EXP OSL (blue curve) and EXP CSQ solutions for both the GBL (full black curve) and the Mediterranean (MED) Mw-mb data sets (full red curve) when assuming a realistic Mw/mb error ratio and b) the proximity of EXP ISL (full green line) and EXP CSQ.

For understanding these partially surprising results one should note that with respect to a) the low magnitude tail with  $m_b < 4.5$  is constrained by only about 10% of the data and no histogram equalization has been applied as by Di Giacomo et al. (2013) and b) that Castellaro and Bormann (2009) already showed that linear orthogonal standard regressions (OSR), which assume both variables to be afflicted with initial errors of the same size, are superior to linear OLS or ISL, respectively, only as long as  $0.7 < \sqrt{\eta_{\text{tru}}} < 1.8$  holds. Outside of this error ratio range either OLS or ISL are even better approximations to the data than OSR and thus closer to GOR. This surely applies to the GBL data set with Mw errors estimated to be on average only 0.4 times the initial errors for mb. Accordingly, EXP ISL is already very close to EXP CSQ, the more so since the average data slope in Fig. 3.70b is already larger than 1, i.e., into the direction of the ISL trend.

Therefore, in summary, one should be cautious when calculating and applying magnitude conversion relationships, avoid over-interpretation of their representativeness and thus the accuracy of proxy magnitude estimates, being aware of the assumptions on which the respective regression relations are based as well as of our usually insufficient knowledge whether our data really meet these conditions.

Accordingly, a few general rules and facts should be taken into account before deciding on the most appropriate regression to be applied:

- Single linear regression relations should only be calculated if an eye assessment of the cloud of available data does not indicate a significant non-linearity within the range of data scatter (e.g., Fig. 3.68).
- If the degree of non-linearity in the data is significant, as in Figs. 3.69, 3.81 and especially 3.82, and thus obvious already by simple eye check of the data, then there exist two opportunities: a) approximating the data in sub-segments by two or more linear curves of different slope, as in Fig. 3.69 or 3.81 or b) by a non-linear regression.
- In the case of modest non-linearity, as in Fig. 3.81, option a) may still yield reasonably good conversion results for practical applications with acceptable average biases  $< 0.1$  m.u. in most parts of the chosen magnitude ranges. However, conversion results will be inconsistent near the discontinuity points where the linear curves with significantly different slope intersect. Therefore, option b), i.e., calculating continuous non-linear regression relations, is generally preferable.
- Non-linear relations between different types of magnitude have two main reasons: a) different degree of spectral saturation, as discussed in conjunction with Figs. 3.5 and 3.45, i.e., when the two magnitudes are measured in ranges of different period and bandwidth and b) if the regression is extended down to magnitudes in which one type is still completely recorded but not the other one, as, e.g., GBL or GCMT Mw for  $M_w < 5.5$  in the case of Fig. 3.70b or Fig. 3.82 (magnitude truncation effect).

- Before deciding on the most appropriate regression procedure one should have an idea about the approximate average measurement errors of the different types of magnitudes compared. Standard least-square regression, which assumes that the chosen independent variable is error-free and all data scatter is related only to the dependent variable is principally not correct. In the case of large data scatter SR1 and SR2 may differ significantly. Therefore, standard regression relationships should not be resolved for the independent variable but used only in the way as they have been derived. If, however, the data scatter is small and the correlation coefficient very large than the difference between SR1 and SR2 may become negligibly small (e.g., in Figs. 3.68 or 3.71, upper right).
- If one has good reasons to assume that both types of magnitudes are measured with similar errors, which is commonly the case for magnitudes based on amplitudes that are measured at comparable periods in similar bandwidth ranges, then orthogonal standard regression (OSR) yields more reliable regression relations than OLS. Yet in the case that the error ratio is  $> 1.8$ , respectively  $< 0.7$ , then SR1, respectively SR2 = ISR, yield better average estimates of the respective proxy magnitude than OSR (see Castellaro and Bormann, 2007). However, in any event, GOR or Chi-squared regressions, linear or non-linear, are in such cases more appropriate, provided that sufficiently reliable average error ratio estimates for the compared magnitudes are available.
- A very important point is to assure, as far as possible, the homogeneity of the regressed magnitude data with respect to the procedures and accuracy with which they were measured over the considered time span and for the considered source area(s). The latter may range from local to regional and global.
- In order to assure that the regression relationship is not biased by the very different data frequency and thus weight in different magnitude ranges histogram equalization should be applied, if sufficient data are available (see Di Giacomo et al., 2013). This has usually not been done.
- Also usually not done, but of utmost importance, is to test the validity of the obtained regression model with values not used in obtaining the model (see Di Giacomo et al., 2013b). Neglecting this may lead to unjustified claims with respect to the accuracy and representativeness of the derived relationships and bears the risk of significantly biased magnitude proxy estimates.
- The accuracy and representativeness of magnitude relationships largely depends on the amount, accuracy, homogeneity and completeness of available data. However, huge amounts of data in a wide magnitude range may be available only when considering large time spans and source areas (global as in section 3.2.9.5, or for regions with very high seismicity). On the other hand, over large time spans magnitude procedures and the accuracy of measurements have rarely been homogeneous and often differed also regionally. Improving the homogeneity and completeness of such long-term global data sets may require labor and time intensive critical data checks and re-computations as practiced in conjunction with the ISC-GEM project for creating a Global Instrumental Earthquake Catalogue (1900-2009) (Storchak et al., 2013; Di Giacomo et al., 2013 a and b).

- On the other hand, relationships between different types of magnitude may vary significantly for different regions. Examples will be given in the following. Therefore, there is a need to derive magnitude regression and conversion relationships also on a regional basis in conjunction with investigations of regional seismicity and seismic hazard. Yet, for many such areas the limited amount of available data, often only for a limited time span and magnitude range, may reduce both their reliability and representativeness for wider areas, time spans and magnitude ranges. Therefore, these “parameters” should always be specified in conjunction with such relationships.
- Nonetheless, we will show in the following also examples for early magnitude relationships that are based on rather limited but homogeneously and competently measured data, sometimes just at a single station or a regional network but still agree for globally distributed events astonishingly well with much more recent relationships based on many more data from global network stations.

### 3.2.9.2 Summary of classical magnitude relationships (P. Bormann)

Gutenberg and Richter (1956a, b) provided correlation relations between various magnitude scales:

$$m = m_B = 2.5 + 0.63 M_s \quad (3.76a)$$

$$m = m_B = 1.7 + 0.8 M_l - 0.01 M_l^2 \quad \text{and} \quad (3.76b)$$

$$M_s = 1.27 (M_l - 1) - 0.016 M_l^2, \quad (3.76c)$$

where  $m$  is the unified magnitude as the weighted mean of the body-wave magnitudes  $m_B$  determined from medium-period broadband recordings. Relationship (3.76a) has become crucial for deriving the Richter (1958)  $\log E_s$ - $M_s$  relationship and via the latter also the  $M_w$  formula by Kanamori (1977) and Hanks and Kanamori (1979).

Practically the same relationship as (3.76a) but based on some more (yet still less than 200 data points) in a wider range of magnitudes between  $5.5 \leq m_B \leq 8.2$  was derived later by Abe and Kanamori (1980):

$$m_B = 2.5 + 0.65 M_s. \quad (3.77)$$

It has only a slightly larger slope than (3.76a) and satisfies the  $m_B$  and  $M_s$  data well between magnitude 5.2 and 8.7.

All these above regression relations are of the SR1 type. Sometimes they were wrongly applied, e.g. in a paper reviewed by the editor, where the author solved Eq. (3.70) for  $M_s$ , then converting short-period  $m_b$  values as published by international data centers into  $M_s$  and finally calculated with these proxy  $M_s$  values the released seismic energy  $E_s$  via the Richter (1958)  $E_s$ - $M_s$  relationships (3.66). Yet, Eq. (3.76a) is suitable only for converting  $M_s$  into  $m_B$  and then applying the only energy-magnitude relationship  $\log E_s$ - $m_B$  which Gutenberg favored [see Eq. (3.95) in section 3.3.2], because he was aware that  $m_B$  determined via  $(A/T)_{\max}$  in a wide range of periods is a much better estimator of released seismic energy than the long-period spectral magnitude  $M_s$  measured at periods around 20 s only.

When using **medium-to-long-period readings of P and surface waves in displacement broadband records of type C (Kirnos SKD)**; see Fig. 3.20) and **SR1 regression**, practically identical relationships to Eq. (3.76a) were found both by Bune et al. (1970) on the basis of records of the former **USSR-wide station network** and by Bormann and Wylegalla (1975) for the **single station MOX** in Germany (magnitude range 4.7 to 8.5). The latter is

$$MPV(C) = 2.5 + 0.60 MLH(C). \quad (3.78a)$$

Relationship (3.76a) could also be reproduced more than 60 years later with practically identical SR1 relationships based on many more modern IASPEI standard mB\_BB and Ms\_BB measurements on velocity broadband readings of globally distributed earthquakes that were recorded by stations of both the China National Seismographic Network (CNSN) and the German Regional Seismic Network (GRSN) (see Bormann et al., 2009 and section 3.2.9.3).

Yet, the related **orthogonal regression** to Eq. (3.78a), calculated for the same data set, is rather different:

$$MPV(C) = 1.83 + 0.70 MLH(C) \quad (3.78b)$$

and the respective best fitting SR2 regression is

$$MLH(C) = -1.54 + 1.25 MPV(C). \quad (3.78c)$$

The latter is clearly different from

$$MLH(C) = -4.17 + 1.67 MPV(C) \quad (3.78d)$$

when resolving incorrectly Eq. (3.78a) for MLH. This would result in an overestimation of MLH by about 1.2 magnitude units for mB = 8 and an underestimation of 0.8 units for mB = 5.

The single random-parameter regression relationship between short-period mb and Ms based on **global WWSSN station network and earthquake data** analyzed at NOAA (with amplitude measurement for mb within the first few cycles only after the P-wave onset) is very different from Eq. (3.76a), namely, according to Gordon (1971),

$$mb = (0.47 \pm 0.02) Ms + (2.79 \pm 0.09). \quad (3.79)$$

This agrees, with a constant offset of -0.16 m.u. (station correction?), with the **single-station** average formula derived by Karnik (1972) for the Czech station Pruhonice (PRU):

$$mb(sp, PRU) = 0.47 MLH + 2.95.$$

On the other hand, when approximating vertical component short-period P-wave MPV(A) values plotted over the related MLV(C) values, both measured for globally distributed earthquakes at the **single station** MOX, Germany, in the wide magnitude range  $4.0 \leq \text{MLV(C)} \leq 8.3$  by shorter overlapping tri-linear orthogonal regression relationships (see Fig. 3.69), Bormann and Khalturin (1975) derived

$$\text{MPV(A)} = 0.91 \text{ MLV(C)} + 0.51 \quad \text{between } 4.0 \leq \text{MLV(C)} \leq 5.5 \quad (3.80a)$$

$$\text{MPV(A)} = 0.72 \text{ MLV(C)} + 1.53, \quad \text{between } 5.1 < \text{MLV(C)} \leq 6.8 \quad (3.80b)$$

and

$$\text{MPV(A)} = 0.45 \text{ MLV(C)} + 3.32 \quad \text{between } 6.1 < \text{MLV(C)} \leq 8.3. \quad (3.80c)$$

The difference between short-period mb and long-period Ms strongly depends on the specifics of the seismic source process, e.g., on differences source size, source-time function, source depth, stress drop and thus radiated seismic spectra, especially the relative ratio of long-period to short-period spectral amplitudes. Therefore, plotting (20 s) Ms over (1 s) mb has become a powerful discriminator between natural earthquakes and underground nuclear explosions (see, e.g., Chapter 11, section 11.2.5.2???, Fig. 11.22???; Figure 5 in Richards, 2002; Figure 2 in Richards and Wu, 2011). A relationship

$$\text{Ms} = 1.25 \text{ mb} - 2.45 \quad (3.81)$$

separates almost all shallow earthquakes globally from underground nuclear explosions (Richards, 2002). Interestingly, its slope is practically identical with the average slope of 1.23 in the Ms range between 4.0 and 6.8 when resolving the orthogonal relationships (3.80a and b) for  $\text{MLV} = \text{Ms}$ . However, the negative constant in (3.81) is 1.34 m.u. larger in order to account for the large data scatter around the average Ms-mb relationship for earthquakes.

Being aware of the even more general potential of Ms-mb, Prozorov and Hudson (1974) proposed a *creepex parameter*

$$c = \text{Ms} - a \times \text{mb} - b \quad (3.82)$$

with a and b being constants to be determined empirically for different source types, stress-drop conditions and seismotectonic regions. *Creep* stands for very slow rupture motions (see *slow* and *silent earthquakes* in the Glossary) and *ex* for explosions or other small seismic sources with extremely short source-time functions. Thus, *creepex* aims at discriminating between normal, very slow and explosion-like (fast rupture high-stress-drop) earthquakes. World-wide determination of this parameter for earthquakes in different regions revealed interesting relations of c to source-geometry and seismotectonic conditions. Global maps of *creepex* have been published by Prozorov et al. (1983) and Kaverina et al. (1996). Prozorov and Shabina (1984) could show that the regional earthquake catalog for Mexico contains earthquakes with rather different *creepex* values, that are related to three major types of tectonic structures. E.g., *Creepex* is positive in zones of spreading and high heat flow, and negative in areas where relatively cold lithospheric plates are subducted into the mantle. Similar systematic regional differences were also reported for  $\text{Ms} - \text{Mw}$  (Ekström and Dziewonski, 1988; Patton, 1998) and  $\text{Me} - \text{Mw}$  (Choy and Boatwright, 1995; Choy and Kirby, 2004; Di Giacomo et al., 2010a; Bormann and Di Giacomo, 2011). Panza et al. (1993) extended the *creepex* concept to Md-ML and applied it to Italy.

Surface-wave magnitudes determined from vertical and horizontal component recordings using the so-called Prague-Moscow calibration function Eq. (3.35) correlated almost 1:1. According to Bormann and Wylegalla (1975), the orthogonal relationship is

$$MLV - 0.97 MLH = 0.19 \quad (3.83)$$

with a standard deviation of only 0.11 and a correlation coefficient of  $r = 0.98$ . This clearly justifies the use of this calibration function, which was originally derived from horizontal amplitude readings, for vertical component (Rayleigh wave) magnitude determinations, too.

When using medium-period broadband data only, the orthogonal regression relation between magnitude determinations from PV and PPV or SH waves, respectively, are almost ideal. Gutenberg and Richter (1956a) had published Q-functions for all three phases (see Figures 1a-c and Table 6 in DS 3.1). Bormann and Wylegalla (1975) found for a global earthquake data set recorded at station MOX the orthogonal fits:

$$MPPV(C) - MPV(C) = 0.05 \quad (3.84)$$

with a standard deviation of only  $\pm 0.15$  magnitude units (see also Fig. 3.68 right) and

$$MSH(C) - 1.1 MPV(C) = -0.64, \quad (3.85)$$

with a standard deviation of  $\pm 0.19$  and magnitude values for P and S waves, which differ in the whole range of MPV(= mB) between 4 and 8 less than 0.25 units from each other. This confirms the good mutual scaling of these original body-wave calibration functions with each other, provided that they are correctly applied to medium-period data only. Regrettably, international data centers do no longer encourage data producers to report also amplitudes from PPV and SH waves for the determination of mB, which was Gutenberg's original intention.

Kanamori (1983) summarized in graphical form the relationship between the various magnitude scales (see Fig. 3.47 in section 3.2.5.2 above). He also gives the ranges of uncertainty for the various magnitude scales due to observational errors and intrinsic variations in source properties related to differences in stress drop, complexity, fault geometry and size, source depth etc. The range of periods for which these magnitudes are usually determined are for mb:  $\approx 1$  s; for MI:  $\approx 0.1 - 3$  s; for mB:  $\approx 0.5 - 25$  s; for Ms:  $\approx 20$  s and for Mw:  $\approx 10 \rightarrow \infty$  s. Accordingly, these different magnitude scales saturate differently: the shorter the measured periods the earlier "saturation", respectively underestimation of magnitude, occurs, i.e., according to the Kanamori graph for mb on average around 6.5, for MI around 7, for mB around 8 and for Ms around 8.5 while Mw does not saturate. This is in good agreement with the general conclusions drawn on the basis of seismic source spectra (see Fig. 3.5). For mb, however, "saturation" will happen clearly later, when the maximum amplitudes are measured really within the whole P-wave train, as recommended by the new IASPEI standards, and not within an a-priori fixed limited measurement time-window after the first arrival of P.

Ambraseys (1990) and Ambraseys and Bommer (1990), in an effort to arrive at uniform magnitudes for European earthquakes, re-evaluated magnitudes in the range  $3 < M < 8$  and

published in 1990b, with more data than in 1990a, the following updated *orthogonal regression relationships* between the various common magnitude scales:

$$0.76 \text{ mb} - 0.66 \text{ mB} = 0.31 \quad (3.86)$$

$$0.75 \text{ mb} - 0.66 \text{ Ml} = 0.51 \quad (3.87)$$

$$0.87 \text{ mb} - 0.50 \text{ Ms} = 1.91 \quad (3.88)$$

$$0.82 \text{ Ml} - 0.58 \text{ Ms} = 1.20 \quad (3.89)$$

with mb being determined according to the ISC procedure from short-period P-wave recordings and mB using medium-period P-wave records. These relations can be solved for either one of the two variables. Other relationships have been published by Nuttli (1985) which allow estimating Ms for plate-margin earthquakes when mb is known. For mb > 5 their results differ less than 0.2 magnitude units from those of Eq. (3.88) when solved for Ms.

The most recent GOR conversion relationships between more than 70.000 global ISC mb and Ms data during the period 1976-2007 have been published by Wason et al. (2012). This relationship reads, when rounded to the nearest second decimal:

$$\text{Ms} = 1.87 \text{ mb} - 4.44 \quad (3.90)$$

with a correlation coefficient  $R_{XY} = 0.84$  and a root mean square  $\text{RMSO} = 0.24$ . This relationship is rather close to the OSR relationship derived by Bormann et al. (2009) (next section) but differs more from Ambraseys and Bommer's (1990) OSR relationship (3.88) for Europe and adjacent areas, when resolved for Ms:

$$\text{Ms} = 1.74 \text{ mb} - 3.02. \quad (3.91)$$

In the latter relationship Ms is of the Ms\_BB type, measured also at regional distances down to 4° and at much shorter than 20 s periods which results in larger Ms values than the dominatingly 20 s Ms(ISC). At mb = 4 the difference is already 0.9 m.u.

Finally, we refer to a recent work by Ristau (2009), who gives both OSR, SR1 and SR2=ISR relationships between mb and Ml for all depth, shallow ( $h < 30 \text{ km}$ ) and deeper earthquakes in New Zealand. The average OSR relationship for all events reads:

$$\text{mb} = (0.94 \pm 0.07) \text{ Ml} - (0.06 \pm 0.07) \quad (3.92)$$

with a distinct difference in slope (1.11 and 0.79, respectively) as well as scatter for shallow and deeper earthquakes.

### 3.2.9.3 Linear orthogonal and standard regressions between IASPEI standard magnitudes (P. Bormann, D. Di Giacomo and S. Wendt)

Bormann et al. (2009) derived the first OSR relationships between the four IASPEI standard magnitudes mb, mB\_BB, Ms\_20 and Ms\_BB. They are based on data of some 400 to 500 globally distributed earthquakes that have been recorded by the China National Seismographic Network (CNSN) and analyzed at the China Earthquake Network Center (CENC) according to the standard procedures recommended by IASPEI (2005 and 2011) and in IS 3.3. Fig. 3.71 and Tab. 3.4 summarize the results. In the Table, besides the OSR

relations, also the related SR1 and SR2 solutions are given with an  $\leftarrow$  instead of  $=$  sign in order to indicate that these relations can only be solved in this direction but not in the opposite one.

With reference to the Das et al. (2012) GOR relation (3.90) the standard  $M_s$ -20-mb OSR relation looks similar and reads:

$$M_s_{20} = 1.82 \text{ mb} - 4.75 \quad (3.93)$$

with  $R_{XY} = 0.891$  and an  $RMSO = 0.21$ . The somewhat steeper slope with a smaller constant in (3.90) is due to the fact that  $mb(ISC)$  saturates already around 7, standard  $mb$ , however, only around 7.5. Accordingly, an  $mb(ISC) = 7$  relates with (3.90) already to an  $M_s = 8.6$ , a standard  $mb = 7$ , however, according to (3.93), only to an  $M_s = 8.0$  but  $mb = 7.5$  to  $M_s = 8.9$ .

However, of much greater importance than the rather noisy and in fact rather non-linear (see section 3.2.9.5) relationship between short-period  $mb$  and  $M_s$  is the relationship between the new standard broadband  $mB_{BB}$  and  $M_s_{BB}$  with respect to the fundamental relationship between  $mB$  and  $M_s$  published by Gutenberg and Richter (1956a and b):

$$mB = 0.63 M_s + 2.5. \quad (3.94)$$

This SR1 relationship is applicable for magnitudes between about 6 and  $<8.5$ . From it follows that  $mB = M_s$  at magnitude 6.75, yet  $mB$  is on average larger at smaller values of  $M_s$  and smaller at larger  $M_s$ . When substituting  $mB$  by (3.94) in the primary Gutenberg-Richter (1956 and b) relationship between body-wave magnitude and released seismic energy (with  $E_s$  in Joule):

$$\log E_s = 2.4 mB - 1.2 \quad (3.95)$$

one arrives at the relationship (3.66) proposed by Richter (1958) (there with a typo) which has been instrumental in the derivation of both the moment magnitude and energy magnitude scales (see section 3.2.7 of this Chapter and Kanamori, 1977; Hanks and Kanamori, 1979; Choy and Boatwright, 1995; Bormann and Di Giacomo, 2011). Accordingly, the whole foundation of modern earthquake size, respectively strength classification essentially rests on it. Therefore, it is of great interest to know, whether the now proposed new IASPEI broadband magnitude standards  $mB_{BB}$  and  $M_s_{BB}$ , which differ slightly from the original Gutenberg  $mB$  and  $M_s$ , can reproduce this relationship nowadays with many more data in a wider magnitude range being now available than at Gutenberg's time.

**Fig. 3.71** Regression relations between new IASPEI standard magnitudes measured at CENC with respect to the ideal 1:1 line. N = number of (x,y) pairs, RXY = correlation coefficient, RMSO = orthogonal root-mean square error, OR = OSR, SR2 = ISR. For formulas see Tab. 3.4. Copy of Figure 11 by Bormann et al. (2009); © Seismological Society of America.

**Tab. 3.4** Relationships between magnitudes determined from global earthquake CNSN data according to the IASPEI (2005) measurement standards. The unresolved OSR with RMSO are printed in bold letters, the rms for the resolved OSR are the uncertainty (standard error) of the estimated magnitude (modified and amended according to Bormann et al. (2009).

The Chinese data presented in Fig. 3.71 (lower right) cover the magnitude range between 4 and 8.8 (with the great majority of magnitudes < 6), i.e., a much larger range than (3.94) or the slightly modified Abe and Kanamori (1980) formula based on strong earthquake records between 1953 and 1977:

$$mB = 0.65 Ms + 2.5. \quad (3.96)$$

None the less, the respective **standard regression SR1** between the two standard broadband magnitudes  $mB_{BB}$  and  $Ms_{BB}$  (**bold blue in Tab. 3.4**) is very similar to both of these formulas :

$$mB_{BB} \leftarrow 0.65 Ms_{BB} + 2.30 \quad (\text{with SD} = \pm 0.23). \quad (3.97)$$

Practically identical with (3.94), however, is a new  $mB_{BB} - Ms_{BB}$  SR1 relationship derived from a global set of 227 earthquakes in the range  $4.7 < Ms_{BB} < 8.9$  recorded by STS2 broadband seismographs of the GRSN network in Germany (see also Fig. 3.72 left):

$$mB_{BB} \leftarrow 0.63 Ms_{BB} + 2.52 \quad (\text{with SD} = \pm 0.28). \quad (3.98)$$

According to (3.97) and (3.98)  $mB_{BB} = Ms_{BB}$  for 6.5 and 6.8, respectively, i.e. close to the 6.75 according to (3.95). When converting values between  $Ms_{BB} = 6.0$  and  $8.5$ , i.e. magnitudes for which (3.95) holds, via the relationship (3.97) into  $mB_{BB}$ , then the differences with respect to (3.95) vary between  $-0.08$  and  $-0.03$  m.u. And when using (3.98) instead, the difference to conversions based on the Gutenberg-Richter formula is constant  $+0.02$  m.u. for all magnitudes and thus practically negligible. And with relationship (3.74) Bormann and Wylegalla (1975) had already shown that **even single station BB body-wave and surface-wave magnitudes from global earthquakes** in the magnitude range 4.7 to 8.5 do essentially reproduce (3.95).

Also the SR1 between  $mB_{BB}$  and  $Ms_{20}$ , with slopes between 0.58 (Chinese data; Fig. 3.71 lower left and Tab. 3.4) and 0.62 (GRSN data; Fig. 3.72 right), still match rather well with Eq. (3.95). Conversion differences for  $Ms_{20}$  between 6.0 and 8.5 range between  $-0.04$  and  $+0.13$  m.u., which is much smaller than the standard deviations for all these regressions that vary between  $\pm 0.23$  and  $\pm 0.28$  m.u.

**Fig. 3.72** Regression relationships between  $mB\_BB$  and  $Ms\_BB$  (left diagram), and  $Ms\_20$ , respectively (right diagram) based on the analysis of global earthquakes recorded by the German Regional Seismic Network (GRSN):. SR1 (dot-broken line and upper inserted formula), SR2 (broken line and middle inserted formula) and OSR (bold black line and lower inserted formula). The gray and light-gray shaded bands indicate the 1- and 2-standard deviation limits around the OSR regression line. Given are also the average standard deviations with which the event magnitudes have been estimated.

The differences, however, to the Gutenberg-Richter (1956a)  $mB$ - $Ms$  relationships is slightly larger when comparing a larger set ( $N = 931$ ) of automatically determined global earthquake  $mB(GFZ) = mB\_BB$  measured by the procedure described in Bormann and Saul (2008) and using stations globally distributed, with the respective  $Ms(USGS)$  data, which is in fact an  $Ms\_20$ . According to Fig. 3.73 the SR1 relationship is

$$mB\_BB = 0.69 Ms + 2.26 \quad (\text{with } SD = \pm 0.28). \quad (3.99)$$

In the magnitude range  $Ms = Ms\_20$  between 5.5 and 8.5, conversions of  $Ms$  into  $mB$  according to (3.99) yield values that are between 0.09 and 0.27 m.u. larger than those derived by using the G-R formula (3.94), but they agree perfectly with the later by Abe and Kanamori (1980) on the basis of more data revised relationship (3.96). The conversion differences between (3.99) and (3.96) vary between  $-0.02$  and  $+0.01$  only. This is insignificant as compared to the measurement errors of these magnitudes.

Yet, the respective orthogonal regressions between  $mB$  and  $Ms$  differ clearly from these classical relationships. For the data in Fig. 3.73 the OSR is:

$$mB\_BB = 0.75 Ms + 1.87 \quad \text{with } RMSO = \pm 0.17 \quad (3.100)$$

and an  $SD = \pm 0.21$  m.u. of the  $mB\_BB$  estimates.

**Fig. 3.73**  $mB(GFZ) = mB\_BB$  over  $M_s(USGS) = M_s\_20$  for a global earthquake-station network data set compiled and processed by J. Saul and Di Giacomo (personal communication, 2010). Different point symbols relate to different types of source mechanism, e.g., the upright open triangles to strike-slip mechanism. The grey full line corresponds to the Gutenberg-Richter SR1 relationship (3.64).

In summary, we rest assured that the new standard magnitudes  $mB\_BB$  and  $M_s\_BB$  do not contradict with the inferences drawn by Richter (1958), and later by Kanamori and others on the basis of the Gutenberg-Richter SR1 relationship (3.94) leading to the derivation of the  $M_w$  standard formula. Modern  $M_s\_20$  and  $mB\_BB$  data, however, do better agree with the Abe and Kanamori (1980)  $mB$ - $M_s$  relationship.

#### 3.2.9.4 Linear orthogonal and standard regressions between IASPEI standard magnitudes and classical $mb$ and $M_s$ with $M_w$ and $M_e$ (P. Bormann, D. Di Giacomo and S. Wendt)

Bormann and Saul (2008) and Bormann et al. (2009), supplemented by data provided by Di Giacomo (2010, personal communication), looked into the OSR and standard regression relationships between IASPEI standard magnitudes with  $M_w$  and  $M_e$  for **global earthquakes recorded by world-wide distributed broadband stations**. Fig. 3.73 plots  $M_w(GCMT)$  over  $mB(GFZ)$  which is an automatically determined  $mB\_BB$  according to the procedure described by Bormann and Saul (2008), in the left panel for a limited early and in the right panel for a greatly extended data set compiled and processed by J. Saul and Di Giacomo (personal communication 2010).

**Fig. 3.74**  $M_w(\text{GCMT})$  over  $mB(\text{GFZ})$  for an initial limited data set (left-hand diagram) and a greatly expanded representative data set compiled and processed by J. Saul and Di Giacomo (personal communication 2010) (right hand diagram). The boundaries of the grey and light gray bands, respectively, in the left hand diagram correspond to one and two standard deviations. Larger positive outliers in  $M_w$  direction in both diagrams are relate to rare very slow tsunami earthquakes and large negative outliers to very energetic ruptures. The read line in the right-hand diagram corresponds to the OSR relation in the left-hand panel according to Bormann and Saul (2008).

The OSR relationship in the left-hand panel of Fig. 3.74 is given by Bormann and Saul (2008) as

$$M_w(\text{GCMT}) = 1.33 mB(\text{GFZ}) - 2.36, \quad (3.101)$$

with  $\text{RMSO} = \pm 0.18$  m.u. and an rms of  $\pm 0.30$  m.u. in the estimated  $M_w$ . The related standard regression SR1, however, is

$$M_w(\text{GCMT}) = 1.21 mB(\text{GFZ}) - 1.45 \text{ with rms} = \pm 0.29. \quad (3.102)$$

and SR2

$$mB(\text{GFZ}) = 0.71 M_w(\text{GCMT}) + 2.08 \text{ with rms} = \pm 0.22. \quad (3.103)$$

We should note, however, that the conversion of available instrumentally measured  $M_w$  data into not available  $mB_{\text{BB}}$  values is not of practical importance at all. Relevant is only the need (or wish) to calculate proxy  $M_w$  estimates from measured  $mB_{\text{BB}}$  or other magnitudes if proper  $M_w$  values are not at all, or - because of longer required data acquisition and processing times - not yet available, e.g., in the context of rapid early warning operations. And then, we have principally the choice to use either the SR1 or OSR regression relationship of  $M_w$  over  $mB_{\text{BB}}$  (or other magnitudes). When comparing long-period  $M_w$  data with other long-period or broadband magnitudes of comparably low initial measurement errors than in any event OSR relations are preferable because they represent more correctly the relationship

between these two magnitudes, although the uncertainty in the estimated dependent variable is of the same order as for the SR1.

In Fig. 3.74 the regression relationships are remarkably good average representations for the vast majority of events despite the very different frequency ranges considered and methodologies applied to measure  $M_w$  and  $mB$ . According to the relationships (3.101) to (3.103)  $mB(GFZ)$  values are on average equal to  $M_w$  between 6.9 and 7.2, larger than  $M_w$  by 0.3 to 0.4 at  $M_w = 6.0$ , and smaller by the same amount at  $M_w = 8.5$ . But **automatically determined  $mB(GFZ)$**  from first arriving P waves is available much earlier than  $M_w(GCMT)$  derived from the analysis of very long-period P, S and surface waves. Therefore, by using relationship (3.101), which compensates best for the systematic trend difference between  $M_w$  and  $mB$ , the latter is used, e.g. in the operational German-Indonesian Tsunami Early Warning System (GITEWS; <http://www.gitews.de>), to get first rough proxy estimates of  $M_w$  within 5 min after origin time.

The respective formulas for the larger data set have been inserted in the right-hand diagram of Fig. 3.74. The OSR relationship reads:

$$M_w(GCMT) = 1.22 mB(GFZ) - 1.73 \text{ with RMSO} = \pm 0.15. \quad (3.104)$$

The related uncertainty of  $M_w$  proxy estimates via  $mB(GFZ)$  is  $SD = \pm 0.24$  m.u. and the average difference of  $M_w$  proxies calculated with either (3.101) or (3.104) is generally less than 0.2 m.u.

An almost identical OSR relationship has been derived by S. Wendt by comparing only 274 **manually derived  $mB_{BB}$**  values for global earthquakes recorded at stations of the German GRSN broadband network with  $M_w(GCMT)$ :

$$M_w(GCMT) = 1.22 mB(GRSN) - 1.68 \text{ with RMSO} = \pm 0.20. \quad (3.105)$$

Fig. 3.75 shows the related data plots together with the OSR, SR1 and ISR relationships and the one and two RMSO error intervals (gray and light gray bands).

Similar relationships have been derived by Di Giacomo (personal communication 2010) between  $mB(GFZ)$ ,  $Me(GFZ)$  and  $Me(USGS)$ . The former  $Me$  data have been calculated with another fully automatic procedure described by Di Giacomo et al. (2008; 2010a and 2010b) while the USGS  $Me$  data are calculated by an off-line procedure described by Choy and Boatwright (1995) and in IS 3.6. In contrast to the GFZ procedure, which does not apply source-mechanism corrections to the measured values, in agreement with other classical magnitude procedures, the USGS procedure applies such corrections. Such theoretically based corrections, however, may have the tendency to overestimate  $Me$ , especially for strike-slip events. Possible reasons have been discussed in section 3.2.7.2. Fig. 3.76 shows plots of  $Me(GFZ)$  and  $Me(USGS)$ , respectively, over  $mB(GFZ)$  with the related OSR, SR1 and  $ISR = SR2$  relationships, which are given as inserts together with their rms values.

**Fig. 3.75** Regression relationships SR1, SR2 = ISR and OSR (see inserted formulas from top to bottom) between  $mB\_BB$ , calculated from broadband records at the German GRSN network, and  $Mw(GCMT)$ . For legend see Fig. 3.72.

**Fig. 3.76** Plots of  $Me(GFZ)$  (left-hand diagram) and  $Me(USGS)$  (right hand diagram) over  $mB(GFZ)$ . Different point symbols relate to different types of source mechanism, e.g., the upright open triangles to strike-slip mechanism.

From Fig. 3.76 it is obvious that the data scatter doubles when accounting for theoretically expected yet purely model-based source-mechanism corrections, primarily for strike-slip (SS) earthquakes. Their share in the left-hand diagram are 323 and in the right-hand diagram 204. Note that in the left-hand diagram the difference between  $mB(GFZ)$ - $Me(GFZ)$  for strike slip events is  $0.13 \pm 0.19$  and for all types of source mechanisms  $0.24 \pm 0.19$ , i.e., an average difference of only 0.11 m.u. In contrast, for event magnitudes plotted in the right-hand diagram the difference between  $mB(GFZ)$ - $Me(USGS)$  for strike slip events is  $-0.15 \pm 0.34$

and for all types of source mechanisms  $0.50 \pm 0.24$ , i.e., an average difference of 0.65 m.u. and a greatly increase data scatter.

Proxy estimates of  $Me(GFZ)$ , however, could be made by using the OSR relationship with the automatically determined  $mB(GFZ)$ :

$$Me(GFZ) = 1.27 mB(GFZ) - 1.98 \quad \text{with RMSO} = \pm 0.11. \quad (3.106)$$

$mB(GFZ)$  is available already within the first few minutes after origin time OT and the standard deviation of the  $Me$  estimate is only  $SD = \pm 0.18$  m.u. This is much better than estimating  $Me(GFZ)$  or  $Me(USGS)$  via OSR conversion relationships with  $USGS Ms = Ms_{20}$ . Such proxy estimates would be uncertain, in terms of SD, by  $\pm 0.28$  m.u. for  $Me(GFZ)$  and, even worse,  $\pm 0.39$  m.u. for  $Me(USGS)$  (see Fig. 3.77), although  $Me(USGS)$  had been scaled to  $Ms(USGS)$  (see Choy and Boatwright, 1995; Choy et al., 2006). The very noisy relationship between  $Me$  and  $Ms$  illustrates, why Gutenberg favoured – intuitively - energy calculations via equation (3.95) based on ground motion velocity related  $(A/T)_{max}$  measurements in a wide period range and not via the Richter  $\log E_S$ - $Ms$  relationship (3.66) solely based on 20 s displacement amplitudes.

**Fig. 3.77** Regression relationships for  $Me(GFZ)$  (left diagram) and  $Me(USGS)$  (right diagram) over USGS  $Ms$ , which is in fact an  $Ms_{20}$ . See inserted formulas for OSR, SR1 and  $ISR = SR2$  with their related rms. Triangles represent strike slip earthquakes, circles all other types of mechanisms.

In view of the large difference between the two established  $Me$  procedures and results the question arises, how these two different approaches of  $Me$  measurement relate to  $Mw$ . Fig. 3.78 presents  $Mw(GCMT)$  over  $Me(GFZ)$  and  $Me(USGS)$ , respectively. Again,  $Me(GFZ)$  correlates better than  $Me(USGS)$  with  $Mw(GCMT)$  at reduced scatter. While at  $Mw = 5.5$   $Me(GFZ)$  values are on average 0.16 m.u. smaller than  $Me(USGS)$ ,  $Me(GFZ)$  is on average 0.16 m.u. larger at  $Mw = 9$ . The OSR relationship  $Mw(GCMT)$  over  $Me(GFZ)$  is on average very close to 1:1, whereas the slope of the respective relationship with  $Me(USGS)$  is clearly less than one. The scatter of  $Me$  with respect to  $Mw$  is mainly due to differences in the  $Mw$ -

scaled release of radiated seismic energy, which is closely related to differences in seismic stress-drop and/or rupture velocity (see, e.g., Kanamori and Brodsky, 2004; Venkatamaran and Kanamori, 2004b; Bormann and Di Giacomo, 2011). It can not be excluded, however, that the much larger data scatter of  $M_e(\text{USGS})$  is at least partially due to a overcorrection for theoretically expected source-radiation effects (see section 3.2.7.2).

**Fig. 3.78** Regression relationships of  $M_w(\text{GCMT})$  over  $M_e(\text{GFZ})$  (left-hand diagram) and  $M_e(\text{USGS})$  (right-hand diagram), respectively. Triangles represent strike slip earthquakes, circles all other types of mechanisms.

Bormann et al. (2009) published regression relations between  $M_w(\text{GCMT})$  and  $M_e(\text{USGS})$  with all 4 teleseismic IASPEI magnitude standards (see Figs. 3.79 and 3.80 and Tab. 3.4). One should recognize, however, that magnitude conversion relationships aimed at catalog homogenization are generally not used for converting  $M_w$  or  $M_e$  to classical magnitudes but rather to use the latter, which are both more frequently and for much longer time-spans available than the more recent physically based magnitudes, into proxy estimates of  $M_w$  and  $M_e$ . And since we give preference to the use of the OSR relationships we have highlighted in Tab. 3.4 those resolved for  $M_w$  and  $M_e$ , respectively, in bold blue.

We realize that, with the exception of  $M_s_{20}$  conversions for  $M_s < 6.8$  and conversions of  $mB_{BB}$  into  $M_w$  with standard deviations  $SD \approx \pm 0.2$ , proxy estimates of  $M_w$  from other classical magnitudes have generally an  $SD \approx \pm 0.3$  and for conversions of classical magnitudes into  $M_e$  even values around  $SD \approx \pm 0.4$ , with the exception of somewhat lower standard deviations when converting  $M_s$  data.

**Fig. 3.79** SR1, SR2 and OR relationships between mb, mB\_BB, Ms\_20 and Ms\_BB over Mw(GCMT). Legend as in Fig. 3.71. (Copy of Figure 13 in Bormann et al. (2009); © Seismological Society of America).

**Fig. 3.80** SR1, SR2 and OR relationships between mb, mB\_BB, Ms\_20 and Ms\_BB over Me(USGS). Legend as in Fig. 3.71. (Copy of Figure 14 in Bormann et al. (2009); © Seismological Society of America).

**Tab. 3.5** Relationships of magnitudes determined from CNSN data according to the new IASPEI measurement standards with  $M_w$ (GCMT) and  $M_e$ (USGS), respectively. Legend as in Tab. 3.4. (modified Table 3 in Bormann et al. (2009).

Other conclusions to be drawn from Figs. 3.79 and 3.80 as well as from Tab. 3.4 and formula (3.105) are:

- According to Fig. 3.79 (lower two diagrams) the relationship between Mw with Ms<sub>BB</sub> and Ms<sub>20</sub>, respectively, is better approximated by a bi-linear OSR.
- While both Ms<sub>BB</sub> and Ms<sub>20</sub> correlate with Mw > 6.5 with a **slope close to 1 (up to about 8.5) the slope is less than 1 for smaller Ms.**
- **At magnitudes < 6.5 Ms<sub>BB</sub> deviates on average less (about half) from Mw than Ms<sub>20</sub>** (for formulas see Tab.3. 4)
- The OSR between Mw and mB<sub>BB</sub> according to the Chinese data in Tab. 3.4 has the same slope of 1.22 as in the formulas (3.104) and (3.105), yields, however, in the whole magnitude range on average Mw proxy estimates that are 0.33, respectively 0..28 m.u. larger than those derived with formula (3.105).
- The orthogonal regression between Ms<sub>BB</sub> and Me in Fig. 3.79 and Tab. 3.4 has a slope near 1:

$$Ms_{BB} = 1.02 Me - 0.21 \text{ with SD} = \pm 0.38 \quad (3.107)$$

and is only somewhat larger (1.06) when plotting Ms<sub>20</sub> over Me.

- This good agreement between Me and Ms is understandable, because the magnitude formula  $Me = (\log E_s - 4.4)/1.5$  has been scaled by Choy and Boatwright (1995) to USGS surface-wave Ms in the wide range between 5.5 and 8.3 , adopting the slope of 1.5 in the Richter (1958) logE<sub>s</sub>-Ms relationship.
- This explains the almost perfect agreement of the SR1 regression mB<sub>BB</sub> - Me in Tab. 3.4:

$$mB_{BB} \leftarrow 0.62 Me + 2.46 \text{ (with SD} = \pm 0.29). \quad (3.108)$$

with the classical Gutenberg-Richter (1956) relationship  $mB = 0.63Ms + 2.5$ , because when deriving the Me formula, Choy and Boatwright (1995) substituted Ms by Me.

These quantitative comparisons between classical and new relationships illustrate that by linking the physically well-defined size parameters M<sub>0</sub> and E<sub>s</sub> with magnitude, both Mw and Me are completely tied to the classical empirical magnitudes of mB and Ms with all their possible biases that are, with the exception of saturation, not yet well known and documented.

The most recent GOR models have been derived by Di Giacomo et al. (2013b) in the framework of the ISC-GEM project for creating a New Reference Global Instrumental Earthquake Catalogue (1900-2009) (see section 3.2.9.5). For the bi-linear  $M_w$ - $M_s$  relationship they read:

$$M_w = 0.67 M_s + 2.13 \quad \text{for } M_s \leq 6.47 \quad (3.109)$$

and

$$M_w = 1.10 M_s - 0.67 \quad \text{for } M_s > 6.47 \quad (3.110)$$

and are comparable with bi-linear standard models obtained from more than 26,000 globally distributed earthquakes by Scordilis (2006):

$$M_w = 0.67(\pm 0.005) M_s + 2.07(\pm 0.03) \text{ with SD} = \pm 0.17 \text{ m.u for } 3.0 \leq M_s \leq 6.1 \quad (3.111)$$

and

$$M_w = 0.99(\pm 0.02) M_s + 0.08(\pm 0.13) \text{ with SD} = \pm 0.20 \text{ m.u for } 6.2 \leq M_s \leq 8.2 \quad (3.112)$$

or the GOR models by Das et al. (2011)

$$M_w = 0.67 M_s + 2.12 \quad \text{for } 3.0 \leq M_s \leq 6.1 \quad (3.113)$$

and

$$M_w = 1.06 M_s - 0.38 \quad \text{for } 6.2 < M_s \leq 8.4. \quad (3.114)$$

All these relationships (3.109) to (3.114), based on some 10.000 to 20.000 data points, are almost identical with the OSR relationships in Tab. 3.4 derived by Bormann et al. (2009) based on only 373 proper  $M_{s\_20}$  event magnitudes determined from Chinese National Network data:

$$M_w = 0.667 M_{s\_20} + 2.18 \quad \text{for } M_s \text{ between } 4.0 \text{ and } 6.5 \quad (3.115)$$

and

$$M_w = 0.943 M_{s\_20} + 0.575 \quad \text{for } M_s > 6.5 \text{ to } 8.8, \quad (3.116)$$

respectively.  $M_w$  proxies calculated with (3.115) differ from those derived by the currently most representative ISC-GEM relationship (3.109) in the magnitude range 4.0 to 6.5 by  $\pm 0.04$  m.u., the respective Das et al. (2011) GOR relationship (3.113) by constant -0.01 m.u. and the Scordilis (2006) relationship (3.111) by constant -0.06 m.u. The differences are larger for magnitudes  $M_s > 6.5$  where all relationships are based on much less data. Yet still  $M_w$  proxy estimates according to Das et al. (2011) agree with the respective ISC-GEM estimates up to  $M_s = 8.5$  within 0.05 m.u, and those by the Bormann et al. (2009) formula within 0.1 m.u.. With -0.18 m.u in  $M_w$  at  $M_s = 8.5$  the Scordilis relationship The largest difference.

Although much inferior as compared to the  $M_w$ - $m_B$ -BB relationships published by Bormann et al. (2009) and above [see formulas (3.101), (3.104) and 3.105) as well as Figs. 3.74, 3.75 and 3.78], in common literature only regression relationship between  $M_w$  and  $m_b$  have been published for converting body-wave magnitudes into  $M_w$  proxies. The reason is that globally operating seismological data centers such as the ISC, NEIC, and GCMT published so far, since the mid 1970s, only shortperiod  $m_b$  body-wave magnitudes.

The most recent  $M_w$ - $m_b$  linear GOR relationship, based on more than 27,000 data points, has been derived by Di Giacomo et al (2013):

$$M_w = 1.38 m_b - 1.79 \quad \text{for } 4.0 < m_b < 7.5 \quad (3.117)$$

It is rather close to the Bormann et al.(2009) OSR relationship, based on just 480 data points:

$$M_w = 1.39 m_b - 1.94 \text{ with SD} = \pm 0.33 \text{ for } 4.5 \leq m_b \leq 7.5 \quad (3.118)$$

The  $M_w$  proxy estimates via (3.117) and 3.118) differ in the range  $4.5 \leq m_b \leq 7.5$  less than 0.1 m.u.

Both relationships, however, differ strongly from the GOR relationship between  $M_w$ (GCMT) and ISC  $m_b$  values published by Wason et al. (2012) with a slope of only 1.13, and even more from the slope of the SR1 relationship by Scordilis (2006), based on more than 40,000 data points:

$$M_w = 0.85 m_b + 1.03 \quad \text{for } 3.5 \leq m_b \leq 6.2 \quad (3.119)$$

These large differences in slope are mainly due to the dataset truncation at  $m_b = 6.2$  by both Scordilis (2006) and Wason et al. (2012).

However, since the standard errors with which event  $M_w$  and  $m_b$  are typically determined ( $\leq 0.1$  m.u. and 0.2 to 0.3 m.u., respectively) are very different, ordinary OSR and GOR, based on the assumption that the ratio of initial errors of the two magnitudes is close to 1, are no longer optimal. Castellaro and Bormann (2007) showed that for standard error ratios  $< 0.7$  the inverse regression relationship, i.e., in our case  $m_b$  over  $M_w$ , is closer to optimal. Bormann et al. (2011) give  $m_b = 0.66 M_w + 1.73$  and Das et al. (2011)  $m_b = 0.65 M_w + 1.65$ . When resolved for  $M_w$  these relationships read for the Bormann et al. (2009) data

$$M_w = 1.52 m_b - 2.62 \quad (3.120)$$

and for the Das et al. (2011) data

$$M_w = 1.54 m_b - 2.54. \quad (3.121)$$

For  $m_b = 7.5$ , which is about the largest value so far measured for standard  $m_b$ , (3.120) and (3.121) would yield  $M_w$  proxy values of 8.78 and 9.01, respectively. These are reasonably large values for such large  $m_b$  values, more likely than those derived via (3.117;  $M_w = 8.56$ ) and (3.118;  $M_w = 8.49$ ). However, proxy  $M_w$  estimate via linear regression relationships with  $m_b$ , which really cannot fit well a highly non-linear data cloud (see Fig. 3.82 in the next section), generally tend to underestimate  $M_w$  for both the strongest and the weakest earthquakes.

Therefore, we do not recommend the conversion of short-period  $m_b$  into long-period  $M_w$ . If it has to be done, for whatever reason, then a non-linear relationship, as presented in the next section, should be used. Yet, in future such  $m_b$ - $M_w$  relationships should be based on new standard  $m_b$  data only. They saturate later and thus reduce the strong non-linear distribution of older  $m_b$  data that have been measured on records with often different responses and within more or less fixed limited time windows after the first P-wave arrival. As one can see from Fig. 3.79, the relation between standard  $m_b$  and  $M_w$  is reasonably linear in a rather large range of magnitudes.

Wason et al. (2012) also published a GOR relationship between  $M_e$  and  $m_b$ :

$$M_e = 1.445 m_b - 2.33. \quad (3.122)$$

It differs strongly from the OSR relationship  $M_e = 1.70m_b - 3.86$  by Bormann et al. (2009), but is very close to the related standard regression (see Tab. 3.4):

$$M_e \leftarrow 1.40 m_b - 2.08 \quad \text{with SD} = \pm 0.38 \text{ m.u.} \quad (3.123)$$

In the range of applicability of (3.122), i.e., for input values of  $5.0 < m_b < 6.5$ , the  $M_e$  proxy estimates differ less than 0.04 m.u. from those derived via (3.123). The latter relationship, however, is applicable up to  $m_b = 7.5$ .

### 3.2.9.5 Non-linear ISC-GEM relationships between $M_s$ and $m_b$ with $M_w$ (D. DiGiacomo and P. Bormann)

The ISC-GEM project aimed at the establishment of a New Reference Global Instrumental Earthquake Catalogue (1900-2009) (see Storchak et al., 2013; Di Giacomo et al., 2013b) made every effort to use uniform procedures of magnitude determination during the entire period of the catalogue. Both surface-wave magnitudes  $M_s$  and short-period body-wave  $m_b$  were recalculated, benefitting from new hypocenters (Bondár et al., 2013), previously unavailable amplitude-period data digitized during this project (Di Giacomo et al., 2013a) and a more reliable algorithm for magnitude computation based on 20% alpha-trimmed median network magnitude from several stations (Bondár and Storchak, 2011). For  $M_s$  up to 1970 several thousands of station magnitudes not available before were processed.

The re-computed  $M_s$  and  $m_b$  values provided an ideal basis for deriving new conversion relationships to moment magnitude  $M_w$ . Therefore, rather than using already published regression models, new empirical relationships were derived using both Generalized Orthogonal Linear and exponential non-linear least-square models to obtain  $M_w$  proxies from  $M_s$  and  $m_b$ . The new models were tested against true values of  $M_w$  and found to be preferable to the linear GOR regressions in computing  $M_w$  proxies for the new ISC-GEM catalog. For more details see Di Giacomo et al. (2013b).

The linear GOR relationships derived by Di Giacomo et al. (2013b) for converting recalculated ISC  $M_s$  and  $m_b$  values into  $M_w$  proxies have been given already in the previous section as formulas (3.109), (3.110) and (3.117), respectively. Below they are plotted together with the non-linear OLS regressions and the median values polygons through the  $M_s$ - $M_w$  and  $m_b$ - $M_w$  data clouds (Figs. 3.81 and 3.82).

**Fig. 3.81** Training dataset set  $M_s$ - $M_w$  with regression models: the exponential model is drawn in purple; the bi-linear GOR model is shown in green. The dashed black polygon curve represents the median values for separated bins. Note the good fit between the exponential model and the median values. (Copy of Fig. 14 of Di Giacomo et al., 2013b, © PEPI )

**Fig. 3.82** Training dataset set  $m_b$ - $M_w$  with regression models: Purple - the exponential model; green - the linear GOR model. The dashed black polygon curve connects the median values for separated bins. Note the good fit between the exponential model and the median values between  $m_b=4.7$  and  $6.5$ . (Copy of Fig. 17 of Di Giacomo et al., 2013b, © PEPI )

Although it is obvious from Fig. 3.81 that fitting the  $M_s$ - $M_w$  data cloud with a bi-linear orthogonal regression is already good enough for obtaining sufficiently reliable  $M_w$  proxy estimates within realistic error limits, such an approach introduces some arbitrariness in the data set separation and also a discontinuity point in the relationships derived. The transition between slope  $\sim 0.7$  and  $\sim 1$  is not sharp at all and the separation, which had been adopted by Scordilis (2006) and Das et al. (2011) at  $M_s = 6.1$ , by Bormann et al. (2009) at  $6.5$  and by Ekström and Dziewonski (1988) even at  $6.8$ , could in fact be moved anywhere in this range. Thus, data pairs in this  $M_s$  range may belong to one or another domain depending on the subjective choice of an author of how the data set was divided into the two domains. This also raises the question on how to consistently map the uncertainty in  $M_s$  to  $M_w$  proxies around the separation of the two linear trends. To approximate sufficiently well the highly non-linear trend in the  $m_b$ - $M_w$  data cloud of Fig. 3.82 one would even need at least three or even four linear GOR regression lines.

In order to avoid this problems Di Giacomo et al. (2013b) fitted a single, continuous regression curve to the two training dataset of data points, using an exponential model of the form  $M_y = e^{(a+b \cdot M_x)} + c$ . As one can see from Figs. 3.81 and 3.82, these exponential curves fit rather well with the median values for separated bins. The regression is performed using a

non-linear ordinary least square algorithm (Bates and Watts, 1988; Bates and Chambers, 1992), which is freely available with the R-language (<http://stat.ethz.ch/R-manual/R-patched/library/stats/html/nls.html> or <http://www.r-project.org/>).

Admittedly, this algorithm does not yield an optimal “orthogonal” fit which accounts for the difference in the (usually not well known) measurement errors of the two variable. Rather, the independent, given and to be converted variable is assumed to be error-free. This, however, means that its errors are projected into the dependent, to be estimated variable, thus accounting for uncertainty of the Mw proxy estimates. Moreover, we have be aware that in our case Mw(GCMT) is, in contrast to mb, already incomplete for values below 5.5. But for the purpose of avoiding censoring effects in the model for a magnitude range where Mw proxy estimates above 5.0 were still needed by the GEM project, Mw values below 5.5 had been added to the data set. We are fully aware, however, that one cannot have a reliable OLS mb-Mw model also for smaller quakes when regressing only Mw(GCMT) values over mb. Rather, as discussed already in section 3.2.9.1, mb tends to scale with Mw at values <4.5-5.0 nearly 1:1. Therefore, one should not use the following relations for converting mb and Ms values below 5.0, respectively about 4.5, to Mw.

Despite these limitations, an important advantage of the models presented below is that histogram equalization has been applied to obtain an equal number of data in magnitude bins of varying size in order to preserve the shape of the distribution in the training and validation sets. The latter were used to compare true Mw values and proxy estimates. Thus it could be proved that on average the agreement between Mw and its proxy estimates Mw(Ms) is in the magnitude range 5 to 8 practically 1:1 with rather low scatter, however bad and noisy for Mw(mb) proxies (compare Figures 15 and 18 in Di Giacomo et al., 2013). This was to be expected from the data plots in Figs. 3.81 and 3.82. Therefore, for the Global Instrumental Earthquake Catalogue (1900-2009), only for a small fraction of earthquakes without Ms measurements, usually for deep earthquakes, Mw(mb) has been calculated from mb values only between 5 and 6. The exponential model to convert Ms to proxy Mw reads as

$$M_w = e^{(-0.222+0.233 \times M_s)} + 2.863 \quad (3.124)$$

and that for converting mb into proxy Mw as

$$M_w = e^{(-4.664+0.859 \times m_b)} + 4.555. \quad (3.125)$$

After all the pros and cons of deriving and using conversion relationship as discussed above in section 3.2.9.4 and by Di Giacomo et al. (2013b), including also verification tests, it is strongly recommended to use in future for converting Ms\_20 type of surface waves from the global data centers only formula (3.124). However, one should refrain from converting mb into Mw proxies, if Ms event data are available. If not, the inferior mb derived Mw proxies should be used and interpreted only with caution. In any event, one should never mix and use with equal weight directly measured Mw and proxy values.

### 3.2.9.6 Relationships for converting local and regional magnitudes into Mw (P. Bormann)

So far we have looked only into relationships between the most common types of instrumentally measured magnitudes with emphasis on the recently approved new IASPEI standard magnitudes. They are mostly teleseismic ones. However, the great majority of events

in national-regional catalogs are local or regional events associated with primarily local (Ml) or duration (Md) magnitude types, often not yet according to standardized rules. Because of this and the regionally highly varying attenuation laws, Ml formulas, even when calibrated to the ML standard, may differ significantly (see DS 3.1). The same applies to Md formulas (3.2.4.5). Yet, also such data are nowadays converted into “unified” moment magnitudes Mw, based on regression relationships not with Mw(GCMT), which is routinely available only for  $M_w \geq 5.5$ , but to regional Mw estimates, down to much weaker events, via spectral parameter analysis (see EX 3.3) instead of fitting long-period waveforms.

A very detailed report about the derivation and use of local-regional event conversion relationships based on both local and teleseismic magnitudes as well as regional and GCMT Mw has been presented by Braunmiller et al. (2005) by way of example for Switzerland. These authors also give average uncertainties for the Mw proxy estimates via such relations. They range between  $\pm 0.2$  for Ml and  $\pm 1.0$  m.u. for the macroseismic magnitude estimates Mms of the Swiss Earthquake Service (SED). This is clearly worse than for any proper direct Mw measure. Yet, Braunmiller et al. derived also average Mw conversion relationships for Ml and Md data published by agencies in neighboring countries, which are relevant for the seismic hazard assessment on the Swiss territory too. This concerns data of the Landeserdbebendienst Baden-Württemberg (LED) and of the University of Karlsruhe (KHE) in Germany, the Laboratoire de Detection Geophysique (LDG) in France, and the Istituto Nazionale di Geofisica e Vulcanologia in Italy (INGV). Interestingly, the local magnitudes of all these institutions scale with a slope of 1 with Mw, however their constants as well as the average uncertainty of the Mw proxy estimates vary strongly, hinting to not standardized level scaling, different degree of reliability of the input Ml (see relationships 3.126), Md (see relationships 3.127), and Mm (relationship 3.128) and thus the incompatibility of the respective agency magnitudes and therefrom calculated Mw proxy estimates:

$$\begin{aligned} M_w &= M_l(\text{SED}) - 0.2 \pm 0.2 = M_l(\text{KHE}) - 0.2 \pm 0.4 = M_l(\text{LED}) - 0.3 \pm 0.4 \\ &= M_l(\text{LDG}) - 0.6 \pm 0.4 = M_l(\text{INGV}) - 0.3 \pm 0.7, \end{aligned} \quad (3.126)$$

$$M_w = M_d(\text{LDG}) - 0.8 \pm 0.5 = M_d(\text{INGV}) + 0.1 \pm 0.5, \quad (3.127)$$

$$M_w = M_{ms}(\text{SED}) \pm 0.5 - 1.0. \quad (3.128)$$

Yet, often published relationships aim not at calculating Mw proxies but at estimating via Ml  $\log M_0$ . The latter we converted with the Mw standard formula (3.68) into Mw-Ml relationships and compiled them together with other regional Mw-Ml relations in Tab. 3.6.

In summary, one realizes that in contrast to most relationships between teleseismic magnitudes with Mw there are no globally representative relationship for converting local magnitudes into Mw. Not only the slopes may differ strongly, between about 0.6 and 1.0, but even when the slopes are comparable, then the constants may differ strongly, up to half a magnitude unit or even more. Striking examples in Tab. 3.6 are the difference between the conversion formulas in Western Canada for events in the continental crust and those in the subducting slab (Ristau et al., 2005), or between NW Turkey and Italy. This highlights the need to base any such local-regional conversion formulas on own careful investigations in the respective area. There is no chance to find a priori well-fitting ones in publications related to other seismotectonic regions, although one might later find out a very close agreement with a formula for another region, as, e.g. Margaritis and Papazachos (1999) for their  $\log M_0$  -  $M_{lsm}$  (SM = strong motion) formula for Greece with that by Hanks and Kanamori (1979) (see Tab. 3.6).

**Tab. 3.6** Linear regression formulas for converting local and regional  $M_l$  into  $M_w$ .  $M_{lSM}$  = strong motion  $M_l$

| $M_w =$                  | $M_l$ range     | Region              | Reference                    |
|--------------------------|-----------------|---------------------|------------------------------|
| $0.61 M_l + 0.85$        | $0 - < 4.5$     | NW Italy            | Bindi et al. (2005)          |
| $0.79 M_l + 1.20$        | $3.5 - 5.8$     | Italy               | Castello et al. (2007)       |
| $0.78 M_l + 0.68$        | $0.5 - 6.0$     | NW Turkey           | Parolai et al. (2007)        |
| $0.80 M_l + 0.93$        | $1.0 - 6.0$     | California          | Chávez & Priestley (1985)    |
| $0.87 M_l + 0.60$        | $2.2 - 5.3$     | Israel              | Shapira & Hofstetter (1993)  |
| $1.00 M_{lSM} - 0.02$    | $3.9 - 6.6$     | Greece              | Margaris & Papazachos (1999) |
| $1.00 M_l - 0.05$        | $\approx 3 - 7$ | Southern California | Thatcher & Hanks (1973)      |
| $1.00 M_l - 0.16$        | $2.7 - 5.9$     | Switzerland         | Braunmiller et al. (2005)    |
| $1.00 M_{lcrust} + 0.06$ | $3.6 - < 5.5$   | Western Canada      | Ristau et al. (2005)         |
| $1.00 M_{lslab} + 0.58$  | $3.6 - 6.0$     | Western Canada      | Ristau et al. (2005)         |

Using general orthogonal regressions (GORs), Gasperini et al. (2013a) calibrated local magnitudes, estimated in Italy by using various methods in different periods of time from 1981 to 2010, with a set of homogeneous moment magnitudes  $M_w$ . Magnitude uncertainties, necessary for the application of GOR methods, were inferred by a trial-and-error procedure based on *a priori* information and empirical regression results. They found that these updated and uniquely processed Italian  $M_l$ - $M_w$  relationships also scale 1:1 in most cases but that their  $M_l$  values underestimate in general  $M_w$  by about 0.1- 0.2 magnitude units.

Besides dominantly linear relationships between  $M_w$  and  $M_l$  one finds occasionally also non-linear ones, e.g., those published by Gusev (1991) and Gusev and Melnikova (1992) (see also Figure 9 in IS 3.7). Another logarithmic one has been published by Wu et al. (2001) for Taiwan:

$$M_l = 4.53 \times \ln(M_w) - 2.09 \pm 0.14, \quad (3.129)$$

and a non-orthogonal non-linear one with a quadratic term included by Parolei et al. (2007) for Northwestern Turkey:

$$M_w \leftarrow (0.95 \pm 0.03) + (0.58 \pm 0.02)M_l + (0.003 \pm 0.004)M_l^2. \quad (3.130)$$

### 3.2.10 Summary remarks about magnitudes and their perspective (P. Bormann)

According to Richter (1935), magnitude was intended to be a measure of earthquake size in terms of the seismic energy  $E_s$  released by the source. Yet, more than 40 years later, Kanamori (1977), in his effort to develop a non-saturating magnitude scale, proposed to relate magnitude to the scalar seismic moment  $M_0$  and thus to the amount of “work” performed by rupturing and displacing the earthquake fault. For estimating energy via  $M_0$  assumed an average stress drop and ratio between  $E_s/M_0$ .

$E_s$ , being proportional to the squared velocity of ground motion, can theoretically be obtained by integrating spectral energy density over all frequencies contained in the transient

waveform, e.g., of the P-, S-, or surface-wave train. This procedure could not be carried out efficiently with analog recordings. Therefore, Gutenberg (1945b and c) assumed that the maximum amplitude observed in a body-wave group was a good measure of the energy density in that arrival. As classical seismographs were relatively broadband displacement sensors, he estimated ground motion velocity by dividing the maximum ground displacement of body-wave phases by their associated periods in the range between some 2 to 20 s for calculating a medium-period broadband magnitude  $m_B$  [see Eq. (3.43)]. But the largest displacement plateau amplitude occurs at somewhat longer periods than the maximum velocity amplitudes (see Fig. 3.5). None the less, according to the published formula, Gutenberg's intention was to measure  $(A/T)_{\max}$  and not  $(A_{\max}/T)$ . For estimating the magnitude  $M_s$  from surface waves, however, Gutenberg (1945a) proposed measuring just the maximum displacement amplitude in the surface-wave train around 20 s, although one finds in pre-1970s station bulletins plenty of surface-wave  $A_{\max}$  data published at periods between some 5 and 60 s (see Fig. 3.35b).. Also Gutenberg used in fact occasionally for his  $M_s$  calculations amplitude readings from bulletins made at periods as low as 12 s and as high as 23 s (Abe, 1981a; Lienkaemper, 1984).

According to Fig. 3.5, the spectral amplitudes sampled around 20 s are reasonably good estimators of the maximum of the source velocity spectrum and thus of  $E_s$  only for magnitudes between about 6 and 8.5 as well as of the maximum displacement amplitude plateau and thus of seismic moment for magnitudes  $< 7.5$ . Richter's  $M_L$  also measures only the displacement amplitude maximum in local earthquake records, typically at frequencies  $< 1$  s. Yet, according to Fig. 3.5, such amplitudes are on average both a reasonably good seismic moment estimator for magnitudes  $< 5$  (see several  $M_w$ - $M_L$  relationships in section 3.2.9.6) and a good estimator of the maximum of high-frequency energy release for magnitudes  $< 6$ .

Further, one should note that all classical calibration functions for  $M_L$ ,  $m_B$  and  $M_s$ , including also the IASPEI standard  $M_s$  formula since 1967 [see Eq. (3.36)], which accepts proper  $(A/T)_{\max}$  measurements in a wider range of periods (3 to 60 s) and distances ( $2^\circ - 160^\circ$ ), do account only for distance- (and for body waves additionally depth-) dependent attenuation but neither for any source-mechanism correction nor for a frequency-dependence of the quality factor  $Q$ . The latter seems to be justified at least for periods  $\geq 4$  s, for which the frequency dependence of  $Q$ , if any, becomes negligible or not separable from other disturbing influences on the measured amplitudes (see Chapter 2, section 2.5.4.2).

Since the pioneering works of Richter (1935), Gutenberg (1945 a, b, and c) as well as Gutenberg and Richter (1956 a, b, and c) magnitudes have become, besides phase identification, onset time readings and source locations derived therefrom, the most important earthquake parameter data published in station bulletins and national as well as international earthquake catalogs. Admittedly, seismic moment tensor solutions, scalar seismic moment  $M_0$ , radiated seismic energy  $E_s$  and strong-motion maps may be of greater scientific interest, giving a more precise, complete and physically based description of the investigated seismic source processes and their static, kinematic and dynamic effects. Yet magnitude data will remain also in future an indispensable, most frequently asked for and practically used earthquake source parameter, for both long-term statistical assessment of seismicity and seismic hazard, as well as for public announcements on earthquakes and tsunamis and for providing a first rapid event assessment to guide disaster management and relief operations. Neither the public, nor decision makers and disaster managers can comprehend and base meaningful actions on physical parameters given to them in the range of many orders of magnitude (in different physical units and with a precision of several decimals). What is relevant in the earthquake disaster context for practical actions are simple integer numbers,

such as intensity degrees related to felt earthquake shaking strength and related damages, ranging from 1 to 7 degrees in Japan or 1 to 12 degrees in most other countries (see Chapter 12), or ground accelerations in decimal fractions of the earth gravity  $g$ , or just magnitudes, always being less than 10 and given with a precision not better than one decimal. Such scales are comprehensible and relate to each other sufficiently well. A higher precision is not required, neither for warning messages nor for decisions related to response, disaster preparedness and mitigation efforts.

Yet, besides still many unsolved scientific issues, e.g., those relating to the improvement and harmonizing of the calibration functions applied, there are three major issues that complicate the proper use and assessment of magnitude data in practice:

- a) The diversity and inhomogeneity of procedures;
- b) Changes of procedures, made by agencies or stations, which have often not been well documented and/or analyzed for their effects, thus disrupting the necessary long-term stability and compatibility of magnitude data that have been published with identical symbols/names;
- c) The current trend to convert all types of magnitudes in catalogues just into  $M_w$ . Often it is not said from which type of magnitudes such proxy estimates of  $M_w$  have been derived and what the different ranges of uncertainties for such proxy estimates are.

#### **Examples for a)**

With the establishment by the United States of the WWSSN in the 1960s and 70s no more medium-period broadband systems, required for the determination of  $m_B$ , had been available in this global network of seismic stations. This global network aimed mainly at lowering the detection threshold for seismic events globally down to body-wave magnitudes of about magnitude 4 (instead of 5 to 5.5 achievable with  $m_B$  for teleseismic events). A magnitude 4 corresponds approximately to that of a well contained underground nuclear explosion (UNE) of about 1 kt TNT equivalent. Yield estimates via such magnitudes as well as best possible discrimination between explosions and earthquakes were other original priority tasks for the WWSSN. These goals were hoped to be best achieved by two band-limited seismograph responses with maximum magnification at periods between about 0.5 to 1.0 s (termed WWSSN-SP) and between about 10 and 20 s (termed WWSSN-LP). For the body waves this necessitated the introduction of another, short-period, scale, termed  $m_b$ , although the measured amplitudes were continued to be calibrated with the same Gutenberg-Richter (1956a) calibration function  $Q(\Delta, h)PV$  for medium- to long-period vertical-component P-wave amplitude readings. Additionally, in the interest of best possible discrimination between UNE or other explosions from earthquakes, it was regulated to measure  $(A/T)_{\max}$  not within the whole P-wave train, as Gutenberg did, but within the first few seconds after the P arrival. Useful, as these modifications in record response and measurement-time window (later again expanded) have been for the purpose of UNE detection and their discrimination from earthquakes on the one hand and the lowering of the global event detection threshold on the other hand, they resulted in the much earlier saturation of  $m_b$ , as compared to  $m_B$ , and thus the underestimation of the size of strong earthquakes if only short-period P-waves were analyzed. And the USGS/NEIC  $M_{s\_20}$  values, based on WWSSN-LP records and the use of the IASPEI standard  $M_s$  formula, show a distinct distance dependence and are not fully compatible with broadband  $M_s$  measured in a wider period and distance range using the same calibration function.

Similarly, other requirement or concepts for classifying the size of seismic events resulted in the development of even more magnitude scales such as the Russian K-class, the duration magnitude  $M_d$  or  $mb_{Lg}$  for near and regional events, or of  $m(P, 1\text{Hz})$ ,  $m(PKP)$ , the mantle magnitude  $M_m$ , the more physically based moment magnitude  $M_w$  and energy magnitude  $M_e$ , the fast  $M_w$  proxy estimators  $M_{wp}$ ,  $M_{wpd}$  and others for teleseismic events, or the assignment of macroseismic magnitude values  $M_{ms}$  to historical earthquakes. The reasons for their development and the specific procedures of their measurement have been outlined in detail in the sections 3.2.4 to 3.2.8. These scales have different precision and are more or less reliable mutually scaled (see, e.g., 3.2.9.2 and 3.2.9.6). This notwithstanding, magnitudes of different kinds will still persist and be required in the foreseeable future to allow the size classifications of seismic events under very different instrumental and environmental conditions and envisaged applications, as, e.g., of  $M_l$  that is measured at periods of particular relevance ( $T \approx 0.1\text{ s}$  to  $3\text{ s}$ ) for earthquake engineers, engineering seismologists and disaster managers. Their proper use, however, requires an understanding of their potentials, limitations, original definitions and mutual relationships. Some of these scales are really important complements, such as the narrow-band magnitudes  $mb$  and  $Ms_{20}$ . Their difference permits to draw essentially the same inferences on kinematic-dynamic differences between seismic events as they can now be made, even better, by comparing  $M_e$  and  $M_w$  (see section 3.2.7.2 and IS 3.5). However, for the ordinary user of magnitude data all these details and the reasons for differences and discrepancies between the different types of magnitude can just not be overlooked and reliably be assessed from the vast literature. The previous sections hopefully can help to alleviate this problem.

### **Examples for b)**

Even more confusing and discouraging are inconsistent and even temporal changes of procedures for magnitude data of the same kind, published with the same magnitude symbol. As outlined in section 3.2.4.1, it was found out only decades later that the  $M_L$  data in California have not been measured consistently. Not properly documented and investigated changes in analog and digital amplitude reading practices resulted in baseline shifts that faked temporal changes in seismicity rates which were misinterpreted as being related to the  $M_w 7.5$  Kern County earthquake of 1952. This led Habermann (1995) to state that: “Such mistakes have the potential to undermine the relationship between the seismological community and the public we serve.”

Less dramatic but still significant have been the changes made at the USGS/NEIC with respect to early years  $mb$  (see example a) when following IASPEI recommendations of 1976 to increase the measurement time window, for great earthquakes up to about one minute, and later by replacing the original WWSSN-SP response with the PDE response which has a somewhat broader relative bandwidth and steeper roll-off towards lower frequencies (see Figure 3 in IS 3.3). And the IDC of the CTBTO uses still another pre-processing filter before measuring its  $mb$ . It has an even higher frequency of peak amplification and still steeper flanks towards lower and higher frequencies. In the extreme case of the great  $M_w 9.3$  Sumatra Andaman earthquake of 2004 these different agencies reported  $mb$  values which differed up to 1.5 m.u.:  $mb(IDC) = 5.7$ ;  $mb(CENC) = 6.4$ ;  $mb(PDE) = 7.2$ .

Such discrepancies between magnitudes of the same type are alarming and unacceptable. The recently adopted IASPEI (2005, 2011, and 2013) standards for the most widely used common types of magnitudes:  $mb$ ,  $mb_{Lg}$ ,  $mb_{BB}$ ,  $M_L$ ,  $Ms_{20}$  and  $Ms_{BB}$  as well as for the calculation of  $M_w$  (see sections 3.2.3.2; 3.2.4.2; 3.2.5.1; 3.2.5.2 as well as IS 3.3) aim at eliminating or at least significantly reducing procedural differences between magnitudes of the same kind.

Magnitudes of the same type as these standard magnitudes but based on different measurement procedures which yield values that differ on average more than 0.1 m.u. from these standard magnitudes have to be published in future with a specifying nomenclature (see IS 3.2). Moreover, seismological agencies publishing magnitude data are requested to give full evidence of their procedures of magnitude determination by filling in the questionnaire in Annex 2 of IS 3.4 and by publishing this information on their related website and/or in their bulletins and deposit it at the main international seismological data centers, such as the ISC and the NEIC. With these measures it is expected to drastically reduce in the foreseeable future heterogeneity and the scatter of magnitude data and to assure improved long-term continuity and stability of magnitude data, thus increasing their value for application and research.

### **Examples for c) and how to alleviate the problem**

One of the most important application of magnitude data is in seismic hazard assessment. One of the essential steps in seismicity and hazard assessment procedures is to estimate the average annual return period of earthquakes of a given magnitude. However, such magnitude-frequency plots would be completely “blurred” if one would take into account and mix all different kinds of magnitudes with their often distinct differences in various magnitude ranges, unless there is a single type of magnitude available which represents best the event “size”. Gutenberg and Richter (1954) have been the first to assess the seismicity of the Earth by means of such magnitude-frequency plots using their single event magnitudes  $M$ . Nowadays, there is widespread consensus that the moment magnitude  $M_w$ , calculated via the measurement parameter *seismic moment*, is a physically reasonably defined non-saturating magnitude well suited for serving as such a unique event size parameter.  $M_w$  also allows to relate the seismic moment, estimated for rare strong historical earthquakes from geologic observations, to  $M_w$  determined from instrumental data (Lee, 2013). The problem, however, is that reliable magnitude-frequency relations require as long as possible a time span covered with complete data, but accurate instrumentally measured  $M_0$  and therefrom derived  $M_w$  values are available only since 1976 (see <http://www.globalcmt.org/CMTsearch.html>), in contrast to other magnitudes such as  $m_B$  and  $M_s$  which have been catalogued since 1900 (see Abe, 1981a, 1984; Di Giacomo et al., 2013a and b; Storchak et al., 2013; <http://www.isc.ac.uk/iscgem>),  $M_l$  since the 1930s and  $m_b$  since the 1960s. Thus, there is a need to make use of available conversion relationships between these different magnitudes and  $M_w$  in order to calculate for each event, for which no directly measured  $M_w$  value is available, a  $M_w$  proxy estimate.

However, no  $M_w$  proxy, based on an average statistical estimate calculated from a noisy data set, can be as good as a directly measured individual event  $M_w$ . Therefore, one should in magnitude-wise unified catalogs flag directly measured and proxy  $M_w$  values differently. This is often not done. Moreover, the conversion relationships for different types of magnitudes may differ strongly (e.g., Figs. 3.81 and 3.82 and Eqs. 3.124 and 3.125), be based on differently reliable regression procedures (e.g., linear or exponential; ordinary least squares; simple or general orthogonal; chi-square). Thus, their proxy estimates may have rather different error ranges and should then be assigned different weights in further use. Therefore, it is strongly recommended that catalogs preserve for all events the originally measured different types of magnitude data, indicate for all  $M_w$  proxies their origin (e.g., converted from  $M_l$ ,  $m_b$ ,  $M_s$  and with which relationship). Only this will allow later to reconstruct or correct values on the basis of improved measurement procedures and/or conversion relationships and permit a more correct assessment of the specific nature and

effects of past seismic event than it would be possible on the basis of their measured or assigned proxy Mw values alone.

The current version of the ISC-GEM Global Instrumental Earthquake Catalog (1900 – 2009) (Storchak et al., 2013; Di Giacomo et al., 2013b, Lee, 2013) assigns different estimated average error classes to its Mw values that range from  $\pm 0.1$  to  $> \pm 0.4$  m.u. They relate to either direct GCMT measurements, Mw proxies from Ms, Mw proxies from mb or Mw from bibliographical search (geological and other evidences). Also for the Swiss regional earthquake catalog, covering Switzerland and adjacent territories in Germany, France, Italy and Austria, a homogeneous moment tensor calibration has been performed, using conversion relationships for 13 different magnitude scales to Mw. The uncertainties for the Mw proxies estimated from data of these different original event magnitudes (mainly Ml and Md besides ISC mb and Ms) range between  $\pm 0.2$  and  $\pm 1.0$  m.u. (Braunmiller et al., 2005). Yadav et al, (2009) gave an example, how catalog pages may look like that preserve the original magnitudes, link unambiguously the used conversion relationships to respective proxy Mw estimates and calculate from a comparison of GCMT event Mw with respective proxy estimates the reliability of such proxies (average differences and standard deviations). This eases the later use and correct assessment of catalog data under very different application and research requirements which may go far beyond the need to calculate magnitude-frequency relationships for seismic hazard assessment. Otherwise, if catalogs are magnitude-wise reduced to Mw it might require for later generations a lot of efforts to reconstruct from station bulletins or other notes the related original event magnitude types, as it took Abe (1981a and 1984) years of work to reconstruct the original mB and Ms values behind the “unified” M values published by Gutenberg and Richter (1954) in “Seismicity of the Earth” or in Duda’s (1965) catalog.

In the following section we summarize a selection of important so-called scaling relationships between magnitudes and a variety of geometric as well as kinematic and dynamic source parameters. In this context we will also look into the need (or not) of revising the currently used formulas for Mw and Me determination in the light of modern data on the relationships between mB\_BB and Ms\_20 with released seismic energy.

### 3.3 Similarity conditions and seismic scaling relations (P. Bormann)

#### 3.3.1 Similarity of seismic sources and the definition and use of seismic scaling relations

The *similarity* of seismic sources over a wide range of magnitude or other “size” parameters are the precondition for the derivation of scaling relationships, e.g., between the shape and level of radiated seismic spectra as a function of frequency, as in Fig. 3.5. Similarity of earthquake ruptures exists under certain conditions of static (geometric) and dynamic similarity. With the assumption of a constant stress drop, e.g., one gets

$$W/L = k_1 \quad \text{i.e., a constant fault aspect ratio} \quad \text{and} \quad (3.131)$$

$$\bar{D}/L = k_2 \quad \text{i.e., constant strain } \alpha. \quad (3.132)$$

One can combine Eqs. (3.131) and (3.132) with the definition of the seismic moment  $M_0 = \mu \bar{D} W L = \mu k_1 k_2 L^3$  and gets  $M_0 \sim L^3$  which is valid for source dimensions smaller than the thickness of the *seismogenic layer*.

In addition there is a dynamic similarity, namely, the rise time  $t_r$  required for reaching the total displacement, i.e., the duration of the source-time function, is

$$t_r = k_3 \times L/v_{cr} \quad (3.133)$$

with  $v_{cr}$  the crack or rupture velocity (see Fig. 3.4). This is equivalent to the Eq. (3.132) of constant strain. Lay and Wallace (1995) showed that this results in period-dependent amplitudes of seismic waves which scale with the fault dimension. For periods  $T \gg t_r$  the amplitude does not depend on fault length  $L$ . This corresponds to the plateau of the "source displacement spectrum". But if  $T \ll t_r$  then the amplitudes scale as  $1/L^2$  or  $f^{-2}$  (see Fig. 3.5). This explains the saturation effect when analyzing frequencies much higher than the corner frequency of the source spectrum.

Both in earthquake and engineering seismology the term "scaling law" is widely used. According to Boore (1983) the Fourier spectrum of an earthquake record can be represented as the product of the source, propagation path and site terms. Then it would be very helpful if the entire source term could be represented by just one parameter, e.g., by assuming similarity of the spectra of all earthquakes. This was first done by Aki (1967) when investigating the dependence of the amplitude spectrum of seismic waves on source size on the basis of two different dislocation models of an earthquake source. One has been the Haskell (1966)  $\omega^{-3}$  model, in which the spectral amplitudes decay well beyond the corner frequency  $f_c$  with the third power, and the other one an  $\omega^{-2}$  model, as in Fig. 3.5. Aki considered the surface-wave magnitude  $M_s$  to be a most suitable parameter for scaling the source spectrum. Later this was commonly substituted by the scalar seismic moment  $M_0$ , as in the Geller (1976) scaling laws for body and surface waves and in Fig. 3.5, or by the moment magnitude  $M_w$ , which itself has been scaled to  $M_s$  (see section 3.2.7.1). According to Aki (1967) the theoretical  $\omega^{-2}$  model agreed better with the observed spectra than the  $\omega^{-3}$  model, which would also imply absolute saturation of spectral amplitudes for  $f \gg f_c$ , as also in the Geller (1976) models, according to which  $m_b$  would already completely saturate at 5.9 and  $M_s$  at 8.0. Yet,  $M_s$  has already been observed up to 8.9 (see, e.g., Bormann et al., 2009) and with respect to  $m_b$  Geller had only pre-1976 values available which were based on amplitude measurements within the first few cycles only, as nowadays still the  $m_b$ (IDC-CTBTO). The IASPEI standard  $m_b$ , however, which always measures the largest amplitude in the whole P-wave train, measures values up to about 7.6.

Beresnev (2001 and 2008) rightly questions the assumption of a strict similarity of earthquake source processes and even Aki (1967) hints already in his pioneering paper to "...some indications of departure from similarity". It is rather obvious from wave physics that low-frequency measures such as the scalar seismic moment  $M_0$ , being according to equation (3.1) only a static measure of earthquake size, or the moment magnitude  $M_w$  derived therefrom, cannot provide direct information about the kinematics and dynamics of the rupture process. While the low-frequency asymptote of the displacement spectrum and thus  $M_0$  are solely controlled by the final static offset of the fault rupture, the actual stress drop (see, e.g., Abe, 1982; Choy and Boatwright, 1995) and rupture velocity (Fig. 3.6 and Venkataraman and Kanamori, 2004a and b) may vary strongly for equal moment earthquakes. These latter source parameters, however, control the corner frequency and with it the relative high-frequency content of the source spectrum and thus the amount of radiated seismic energy per unit of  $M_0$

(see Fig. 3.15). Therefore, the single source parameter scaling of seismic spectra is not a viable model and we will look into the scaling problem in a wider context.

We should always keep in mind that ANY earthquake model is a (usually gross) simplification of the complex earthquake rupture process. Models tend to reduce as much as possible the number of controlling parameters, for which usually no directly measured and sufficiently accurate empirical data available and in order to make the models tractable. A good example may be the extensive debate by Scholz (1994 a and b), Romanowicz (1994), Romanowicz and Rundle (1994) and Sornette and Sornette (1994) about a paper by Scholz (1982) dealing with the scaling laws for large earthquakes. He interpreted the observation that the mean slip in large earthquakes is linearly proportional to fault length  $L$  and does not correlate with fault width  $W$  on the basis of two possible models for large earthquakes: a)  $W$  models, in which stress drop and slip are determined by fault width  $W$  and b)  $L$  models, in which these two parameters are fundamentally determined by  $L$ . But both models come to opposite conclusions with respect to mean particle motion and rise time of the source-time function. In a later paper Scholz (1997) could show, however, that such conflicts do not exist when the size distribution of faults is properly taken into account. Wang and Ou (1998), using the large data base by Wells and Coppersmith (1994), argued that  $W$  is independent of  $L$  for large earthquakes, that average displacement  $\bar{D}$  relates to  $L$  as  $\bar{D} \sim L$ , seismic moment to  $L$  as  $M_0 \sim L^2$  whereas  $\bar{D}$  is independent of  $W$ . Accordingly, they concluded that the  $L$ -model proposed by Scholz (1992) is more appropriate than the  $W$ -model suggested by Romanowicz (1992) to describe the scaling of earthquake faults.

In any event, a rectangular fault plane is nothing but a rough approximation of a more or less irregularly shaped rupture area for medium to strong size earthquakes. According to Geller (1976), empirical data for earthquakes are agreeable with assuming an average aspect ratio  $L/W = 2$  with a scatter of about 2. Purcaru and Berckhemer (1982), however, assume for great earthquakes aspect ratios even up to 30. The “true”  $L/W$  depends on the rupture dimensions with respect to the thickness  $h_{sg}$  of the seismogenic zone in the Earth crust, respectively lithosphere, which is capable of brittle fracturing.  $h_{sg}$ , however, depends on crustal thickness, age and heat flow conditions, which vary from region to region. In California, with its young crust and high heat flow,  $h_{sg}$  is only about 12 to 15 km. Deeper earthquakes hardly ever occur. The maximum width of an earthquake rupture is  $W_{max} = h_{sg}/\sin\delta$ , with  $\delta$  the fault dip. Accordingly, the ratio  $L/W$  may vary between about 1 and about 10, or even more, e.g., for mega-events such as the great Mw 9.3 Sumatra-Andaman earthquake of December 2004 with a rupture length of about 1300 km.

If one defines, according to Scholz (1982), as small earthquakes those which have a source radius  $r \leq W_{max}/2$ , then they likely can be represented reasonably well by assuming even circular fault planes with radius  $r$  in an elastic medium, whereas large earthquakes with  $r > W_{max}/2$  are better treated as rectangular ruptures with one edge at the free surface and only  $L$  growing with magnitude.

Yet, even when using only circular source models for deriving some crucial source parameters from seismic spectra, such as source radius  $r$ , rupture area  $A$ , average displacement  $\bar{D}$  and stress drop  $\Delta\sigma$ , then the calculated values may differ significantly even for identical input values of  $M_0$  and  $f_c$  estimated from identical seismic spectra. E.g., the most common models by Brune (1970) and Madariaga (1976; models I and II) yield values for these inferred parameters that differ by factors between about 1.7 and 6 (see EX 3.4). Model inherent uncertainties in this range or even larger ones should therefore be kept in mind when using the scaling relationships. The main advantage of using quantifiable models is not that

they tell us the absolute truths with respect to the derived parameters but that they reveal, in a consistent and reproducible manner, relative differences between these parameters for different events, provided that the model assumptions hold for all of them, and to assess their variability with magnitude, space and time.

In the following we present a selection of various relationships between magnitudes with physical or geometrical parameters of the seismic source, such as radiated seismic energy and seismic moment, stress drop, duration of rupture, area or length and width of rupture, fault dislocation, or between magnitudes and earthquake effects at some distance from the source, such as the area of felt shaking, or the intensity of shaking as a function of distance from the source (attenuation laws). If any of these parameters appears to be related in a systematic and predictable manner over a wide range of earthquake size, scaling “laws” based on similarity conditions may be inferred. Seismic scaling laws then allow to roughly estimate one parameter from another (e.g.,  $E_s$  from magnitude, or  $M_0$  from field evidence such as surface rupture length and/or displacement). Therefore, the knowledge of theoretically well founded scaling laws or empirical scaling relationships is of crucial importance for both probabilistic and deterministic seismic hazard analyses. They aim at assessing the future earthquake potential of a region on the basis of data from past events, dating back as far as possible.

Scaling laws are often the only way to estimate parameters of historical earthquakes for which no instrumental measurements of magnitude, seismic energy or scalar seismic moment are available. Specifically, one often has to make reasonable estimates of the size of the largest earthquake that might have occurred at or could be generated by a particular fault or fault segment and of the kind of seismic spectrum it might (have) radiate(d). However, as stated above, seismic sources differ not only in their geometrical size, shape, aspect ratio, rupture velocity and average slip. Ambient stress conditions and stress drop, the dominant modes of faulting and related seismic source spectra may also differ significantly from region to region. For instance, events of the same seismic moment may radiate seismic energies which differ by 2 to 3 orders (see sections 3.1.2.3 – 3.1.2.5, 3.2.7.2 and IS 3.5). Therefore, globally-derived scaling relations may not be appropriate for use in some areas or outside the magnitude/size ranges for which they have been derived. Regional scaling laws should be used, therefore, whenever available, particularly when inferences have to be drawn on regional seismic strain rates, and seismic hazard, the latter being mainly controlled by the frequency of occurrence and the potential of earthquakes to generate strong high-frequency motions.

### 3.3.2 Relationships between seismic energy, seismic moment and magnitudes (P. Bormann and D. Di Giacomo)

Gutenberg (1956) proposed the following relationship between seismic energy  $E_s$  (in units of Joule ;  $1 \text{ J} = 10^7 \text{ erg}$ ) and the so-called unified body-wave magnitude  $m$ , which he measured in a wide range of periods between about 2 and 20 s and later renamed  $mB$ :

$$\log E_s = 2.4 m - 1.2. \quad (3.134)$$

Eq. (3.134) is based on a rather small data set (see Fig. 3.83). Gutenberg (1956) estimated the error in  $\log E_s$  calculated via (3.134), which is in fact not a proper standard regression relation, to be “*probably less than one unit.*” Together with  $mB = 2.5 + 0.63 M_s$  in Gutenberg and Richter (1956a), Eq. (3.134) yields

$$\log E_S = 1.5 M_s + 4.8. \quad (3.135)$$

**Fig. 3.83** Primary relation, between seismic energy  $E_S$  as a function of the “unified” magnitude  $m$ , as published first by Gutenberg (1956).  $m$  is an average weighted event  $m_B$ .

Eq. (3.135) was first proposed by Richter (1958), however published with a printing error in the constant (4.4 instead of 4.8). Up to now it is the most widely applied relationship between seismic energy and magnitude and generally referred to as a Gutenberg-Richter relationship. One should be aware, however, that Gutenberg preferred and authorized with any of his own - or co-authored - publications only Eq. (3.134). In Gutenberg and Richter (1956b) he stated that “*Present studies are directed toward a scale based on the quotient ( $A/T$ ) rather than on amplitudes. ...It is believed that magnitudes determined from body waves of teleseisms are more coherent with the original scale than those from surface waves, which have been in use as the general standard*”. The reason is that  $m_B$ , determined by measuring  $A/T$  in a wide range of periods, is more directly related to ground motion velocity and thus to seismic energy released by earthquakes in a wider range of magnitude than  $M_s$ , which is measured around 20 s only. Kanamori (1977), however, when investigating the energy release in great earthquakes and developing the concept of a non-saturating seismic moment magnitude  $M_w$  (see 3.2.5.3), considered only Eq. (3.135) because of the long corner periods of strong and great earthquakes.

Later, with more  $M_s(20)$  data of the NEIC in a wider magnitude range being available as well as direct  $E_S$  determinations from analyzing broadband velocity records (see IS 3.6) Choy and Boatwright (1995) found

$$\log E_S = 1.5 M_s + 4.4. \quad (3.136)$$

be a better approximation to the data, confirmed also by later compilations with many more data (Choy et al., 2006; see Fig. 3.84).

**Fig. 3.84** Relationship between radiated energy  $E_S$  and  $M_s$  as calculated by the USGS. (Copy of Figure 1 by Choy et al. (2006) in Abercrombie R., McGarr, A., and Kanamori, H. (eds): Radiated energy and the physics of earthquake faulting, *AGU Geophys. Monogr. Ser.* **170**, p. 45; © American Geophysical Union).

However, Eq. (3.136) and the respective regression line in Fig. 3.84 did not result from an optimal least square fit through the data. Rather, in the interest of assuring widest possible continuity with Eq. (3.135) and the later definition of the  $M_w$  scale, on which decades of research results rest, these authors preferred to revise only the constant by looking for the best fitting 1.5-slope line through the  $E_S$ - $M_s$  data cloud. Yet, when searching for best fitting orthogonal linear regressions through modern  $\log E_S$ ,  $mB(BB)$  and  $M_s(20)$  data, then rather different relationships have been found [see Figs. 3.85 and 3.86 and relations (3.137) to (3.140)].

**Fig. 3.85** Comparison of Gutenberg's (1956)  $\log E_s$ -mB relationship (blue hatched-3dot line) with standard (SR and ISR) and orthogonal (OR) regression relationships (black lines; hatched, hatch-dotted and full line, respectively) between  $\log E_s$  and automatically measured IASPEI standard mB\_BB values according to the GFZ procedure described by Bormann and Saul (2008). The mB data were kindly provided by J. Saul in 2010. **Left:**  $\log E_s$ (GFZ) is based on  $E_s$  determined by applying the automatic GFZ procedure for processing broadband velocity records as described by Di Giacomo et al. (2010 a and b); **Right:**  $\log E_s$ (GS) is based on  $E_s$  values published by the US Geological Survey (USGS). They are determined interactively according to the procedure described by Choy and Boatwright (1995) as well as in IS 3.6. The colored data point symbols relate to different types of source mechanism as in the legend at the upper left. For formulas see lower right inserts.

**Fig. 3.86** Comparison of Choy and Boatwright's (1995)  $\log E_s$ - $M_s$  relationship (brown hatched-3dot line) with standard and orthogonal regression relationships (symbols as in Fig. 3.87) between  $\log E_s$  values determined at the GFZ (left) and the US Geological Survey (USGS) (right), respectively, with USGS  $M_{s,20}$  values. The Richter (1958) relationship  $\log E_s = 1.5 M_s + 4.8$  would be parallel to the C&B line but 0.4  $\log E_s$  units higher.

The following conclusions can be drawn from Figs. 3.85 and 3.86:

- $\log E_s$ (GFZ) correlates much better than  $\log E_s$ (USGS) with both IASPEI standard mB(BB) and  $M_s(20)$ . The reason is that the GFZ procedure, in contrast to that of the USGS, does not apply any source mechanism corrections, which are not common for all classical magnitude scales. Such corrections to  $\log E_s$ (USGS) produce the large average off-set between the data points for strike-slip earthquakes which Choy interpretes in terms of exceptionally large apparent stress, respectively stress drop, in strike-slip environments (see IS 3.5).
- The slopes and constants of the standard OR regression relations through modern  $\log E_s$  data differ significantly from the original Gutenberg and Richter (1956a)  $\log E_s$ -mB relationship in Eq. (3.135). Remarkably, however, the latter is a rather good average fit through the  $\log E_s$ (USGS) data for strike-slip earthquakes in Fig. 3.86 right. For other types of source mechanisms, however, it would overestimate  $\log E_s$  on average by about 1 unit.

- The  $\log E_S(\text{GFZ})$ - $mB(\text{GFZ})$  OR relationship has a very high correlation coefficient  $R_{XY}$  and a small orthogonal rms (RMSO). It reads:

$$\log E_S(\text{GFZ}) = 1.92 mB(\text{GFZ}) + 1.39 \text{ with RMSO} = 0.13. \quad (3.137)$$

Values of  $\log E_S$ , calculated with (3.137) from  $mB$ , are at  $mB = 6.0$  and  $8.3$  about  $-1.3$  and  $-2.4 \log E_S$  units smaller than those derived via the Gutenberg-Richter formula (3.135), which yields already constantly values that are  $0.4$  units larger than those derived by the Choy and Boatwright (1995) relation (3.136).

- The  $\log E_S(\text{USGS})$ - $mB(\text{GFZ})$  OR relationship has a much larger RMSO:

$$\log E_S(\text{USGS}) = 2.60 mB(\text{GFZ}) - 3.54 \text{ with RMSO} = 0.30. \quad (3.138)$$

- Values of  $\log E_S$ , calculated with (3.138) from  $mB$ , are at  $mB = 6.0$  and  $8.3$  about  $-1.1$  and  $-1.7 \log E_S$  units smaller than those derived via the Gutenberg-Richter formula (3.135).
- The much larger and not random scatter of  $\log E_S(\text{USGS})$  data explains the large slope offset between the orthogonal and SR1 standard regression relations (see Fig. 3.86 right). This offset is almost negligible for the  $\log E_S(\text{GFZ})$ - $mB$  relationship (see Fig. 3.86 left). For general discussion of the relationship between SR, ISR and OR see Bormann et al. (2007) and Castellaro and Bormann (2007).
- The large difference between the regression relationships based on apparently the same type of  $\log E_S$  data highlights again the importance to specify with a unique nomenclature different procedures applied to calculate such data. Otherwise, procedural effects might be misinterpreted as being effects of real nature or the latter might be hidden due to procedural noise.
- The differences between the Richter (1958)  $\log E_S$ - $M_s$  relationship and the regression relations between different versions of  $\log E_S$  and  $M_s(20)$  are less pronounced yet still significant.
- The orthogonal regression between  $\log E_S(\text{GFZ})$  and  $M_s(20)$  of the USGS confirms almost perfectly the Choy and Boatwright (1995)  $\log E_S$ - $M_s$  relationship in Eq. (3.136). It reads:

$$\log E_S = 1.51 M_s + 4.51 \text{ with RMSO} = 0.24 \quad (3.139)$$

and yields in the whole considered magnitude range between  $M_s 5.2$  and  $8.8$  values of  $\log E_S$  that are only between  $+0.16$  and  $+0.20$  units of  $\log E_S$  larger than those calculated via the Choy and Boatwright (1995) formula (3.136). This is within the uncertainty range of energy calculations in general.

- In contrast, despite still reasonably good agreement between the orthogonal  $\log E_S(\text{USGS})$ - $M_s$  relationship

$$\log E_S = 1.79 M_s + 2.41 \text{ with RMSO} = 0.30 \quad (3.140)$$

and (3.136) for medium-size earthquakes, the differences for converting  $M_s$  into  $\log E_S$  reach for  $M_s = 5.2$  and  $8.8$  values of  $-0.42$  and  $+0.56 \log E_S$  units, respectively, which is unacceptably large. Thus, the orthogonal regression between  $\log E_S(\text{GFZ})$  and  $M_s(\text{USGS})$  constrains the Choy and Boatwright (1995) formula (3.136) much better than the orthogonal regression between  $\log E_S(\text{USGS})$  and  $M_s(\text{USGS})$  or the conditional regression applied by these authors to their data (see Fig. 3.84 and related comments).

- When substituting in the relationships (3.139) and (3.140)  $M_s$  by  $M_e$ , as done by Choy and Boatwright (1995) when deriving the currently applied  $M_e$  standard formula (3.72)  $M_e = (\log E_s - 4.4)/1.5$ , then relationship (3.139) would yield

$$M_e = (\log E_s - 4.51)/1.51 \quad (3.141)$$

and (3.140)

$$M_e = (\log E_s - 2.41)/1.79. \quad (3.142)$$

- When calculating for  $\log E_s$  values of 12 and 18, corresponding to  $M_e$  values of approximately 5 and 9, via relationship (3.141)  $M_e$  then the values are in this  $\log E_s$  range only between 0.11 m.u. and 0.14 m.u. smaller than values calculated with the current  $M_e$  formula (3.72). In contrast, relationship (3.142) yields values that differ in this range between +0.40 m.u. and -0.36 m.u.
- Moreover, the RMSO scatter of  $\log E_s$ (GFZ) over both USGS  $M_s$ (20) and  $mB$ (GFZ) is significantly smaller than that of  $\log E_s$ (USGS). This questions, within the unavoidable range of data scatter, the suitability of applying mechanism dependent corrections in the USGS procedure to the calculated  $E_s$  values, or at least the size of such corrections applied to strike-slip earthquakes and to more high-frequency data for smaller earthquakes in general.

The latter point has repeatedly been discussed, e.g., by Newman and Okal (1998), Pérez-Campos and Beroza (2001), and Bormann and Di Giacomo (2011). Also Okal and Talandier (1989) pointed out that a “*..magnitude concept, which ignores the exact focal geometry, could be a more robust measure of the true size of the event than one correcting for an expected small source excitation, but failing to account for non-geometrical effects*” such as scattering or multi-pathing of energy in inhomogeneous media. Moreover, calculated average point-source fault-plane solutions are afflicted with unavoidable uncertainties in the order of several degrees (up to about 10°). Also, the orientation and radiation pattern of sub-segments of rough non-planar faults and rupture irregularities may significantly differ from those calculated for planar point source fault-plane solutions. Such non-accountable details in real Earth and earthquake ruptures, however, effect especially higher frequencies that largely contribute to the  $E_s$  estimates, the more the smaller the earthquakes and the radiated wavelength are. This may also explain why Schweitzer and Kverna (1999) could not prove any significant influence of source radiation patterns on globally observed short-period  $m_b$  estimates.

Finally, we again make the point that it is rather arbitrary to scale the energy magnitude  $M_e$ , based on  $E_s$  estimates resulting from the integration of squared velocity broadband P-wave records in a wide range of periods between about 1 and 100 s, to narrow-band long-period surface-wave magnitude  $M_s_{20}$ . This was surely not the intention of Gutenberg (1956) when he proposed (3.134) based on body-wave magnitude measurements in a wide range of period. This inappropriate scaling can only be understood by the fact that during the decades of WWSSN dominated seismology no more medium-period broadband records were available in the “Western World” and measuring “old-fashioned” broadband  $mB$  was just out of debate. Yet, with  $mB_{BB}$ , based on velocity-broadband P-wave records, being now again a IASPEI recommended body-wave magnitude standard that “saturates” much later than short-period  $m_b$ , it is strongly recommended to reconsider the scaling of  $M_e$  to  $mB_{BB}$  instead to long-period  $M_s_{20}$ . Also Abe (1982) came to the conclusion that the size of earthquakes, both deep and shallow, is consistently quantified by the amount of seismic energy expressed by the broadband body-wave magnitude  $mB$ .

When following the practice of Kanamori (1977) and Choy and Boatwright (1995) of substituting  $M_s$  by  $M_w$ , respectively  $M_e$ , when deriving (3.68) and (3.72), then the respective  $\log E_S$ -mB relationships (3.138) and (3.139) would yield the following alternative  $M_e$  relationships:

$$M_e = (\log E_S - 1.39)/1.92 \quad (3.143)$$

and

$$M_e = (\log E_S + 3.54)/2.60. \quad (3.144)$$

Considering the same range of  $\log E_S$  between 12 and 18 as above, then, when compared with  $M_e$  values calculated by the current  $M_e$  formula (3.72), (3.143) would yield values that differ between +0.46 m.u. und -0.42 m.u., and (3.144) values that differ even more, namely up to +0.91m.u. and -0.79 m.u., respectively. At values around 7.6, however, the current  $M_s$ -scaled and new mB-scaled  $M_e$  values would agree well. This makes sense, because according to the scaling law in Fig. 3.5, right panel, the average seismic source velocity spectra have their maximum velocity amplitudes at this magnitude on average around 20 s periods.

The general conclusion to be drawn from such a reasonable rescaling of the broadband body-wave  $M_e$  to broadband mB is, however, that the current  $M_s$ -scaled  $M_e$  formula may significantly underestimate  $M_e$  at magnitudes less than 7.6 and overestimate  $M_e$  for stronger earthquakes. Yet, such a physically logical and even demanding rescaling of  $M_e$  would question many of the conclusions derived since the 1990s from  $\log E_S$  and  $M_e$  data calculated on the basis of their current scaling to  $M_s$ .

We will now refer to some earlier results and considerations on other  $\log E_S$ -magnitude relationships. From theoretical considerations, Randall (1973) derived a relationship between  $E_S$  and the local magnitude  $M_l$  which was later confirmed empirically by Seidl and Berckhemer (1982) as well as by Berckhemer and Lindendorf (1986). On the basis of direct energy calculations for earthquakes from the Friuli region, Italy, using digital broadband records of the Gräfenberg array in Germany, the latter obtained:

$$\log E_S \sim 2.0 M_l. \quad (3.145)$$

This is close to the empirical findings by Gutenberg and Richter (1956a) ( $\log E_S \sim 1.92 M_l$ ) for southern California and the more recent one by Kanamori et al. (1993). The latter found

$$\log E_S = 1.96 M_l + 2.05 \quad (3.146)$$

in the magnitude range  $1.5 < M_l < 6.0$ . For  $M_l > 6.5$   $M_l$  saturates.

For short-period body-wave magnitudes mb, Sadovsky et al. (1986) derived the relationship

$$\log E_S = 1.7 mb + 2.3 \quad (3.147)$$

that is applicable for both earthquakes and underground explosions. **Note:** According to the slopes in the above equations one unit of magnitude increase in  $M_s$ , mb,  $M_l$  or mB, respectively, corresponds to an increase of  $E_S$  by a factor of about 32, 50, 100 and 250 times, respectively!

In this context one should mention that in the countries of the former USSR the energy scale after Rautian (1960),  $K = \log E_S$  (with  $E_S$  in J), is widely used and given in the catalogs. It is based on the same elements as any other magnitude scale such as an empirical calibration

function and a reference distance (here 10 km).  $K$  relates on average to magnitude  $M$  approximately via

$$K = 1.8 M + 4. \quad (3.148)$$

Riznichenko (1992) summarized data and relationships published by many authors (see Fig. 3.87) between magnitude  $M$  and  $K$  on the one hand and  $\log M_0$  on the other hand. Depending on the range of distance and size,  $M$  stands here for  $M_L$ ,  $m_b$ ,  $m_B$  or  $M_s$ . For more details on  $K = \log E_s$  and other types of magnitude see section 3.2.4.6 and IS 3.7.

### 3.3.3 Relationship between $M_0$ , $E_s$ and magnitude

(P. Bormann and D. Di Giacomo)

Kanamori (1983) published linear relationships between  $\log E_s$  and  $\log M_0$  for both shallow and intermediate to deep events (see Fig. 3.88). These two relationships are rather similar and correspond, on average, to a ratio of moment scaled energy of  $E_s/M_0 = 5 \times 10^{-5}$ , or, according to Okal and Talandier (1989), to a so-called “slowness parameter”  $\Theta = \log (E_s/M_0)$  of -4.3. Kanamori (1977) assumed this value to be representative for global earthquake sets and used it for developing the moment magnitude scale  $M_w$ . However, as previously mentioned in the sub-sections 3.2.7.1 and 3.2.7.2 on moment and energy magnitudes, scaling laws based on a constant ratio  $E_s/M_0$  must be used with great caution. Later investigations revealed sometimes significant deviations from the Kanamori ratio of  $E_s/M_0$  (e.g., Kikuchi and Fukao, 1988; Choy and Boatwright, 1995; Bormann and Di Giacomo, 2011). Variations in  $E_s/M_0$ , respectively  $\Theta$ , are mainly due to local and regional differences in source mechanism, related stress drop, rupture velocity and time history of the rupture process.

**Fig. 3.87** Correlation between seismic moment  $M_0$  (in  $\text{Nm} = \text{J}$ ), magnitude  $M$  and Rautian's (1960) energy class  $K$  according to a compilation of data from many authors. Related stress drop  $\Delta\sigma$  has been given in MPa (full straight lines). Broken lines mark the 68% confidence interval. 1 - large global earthquakes; 2 - average values for individual regions; 3 - earthquakes in the western USA; 4 - micro-earthquakes in Nevada; 5 -  $M_0$  determinations from field data;

6 to 15 - individual values from different regions (modified from Riznichenko, 1992, Fig. 1; with permission from Springer-Verlag).

**Fig. 3.88** Relations between seismic moment  $M_0$  and energy  $E_s$  for shallow events (left) and intermediate to deep events (right) according to Vassiliou and Kanamori (1982). The solid line indicates the relation  $E_s = M_0 / (2 \times 10^4)$ , which had been suggested by Kanamori (1977) on the basis of elastostatic considerations (modified from Kanamori, 1983 in *Tectonophysics*, Vol. 93, p. 191 and 192, with permission from Elsevier Science).

Fig. 3.89 depicts the  $\Theta$  values for a large global event data set, plotted over  $M_w$  and calculated as the difference between  $\log E_s$  (USGS=GS) (upper panel), respectively  $\log E_s$  (GFZ) (lower panel), and  $\log M_0$  (GCMT). Note the difference in data scatter and in average  $\Theta$  values:  $\Theta$ (Kanamori, 1977) = -4.3,  $\Theta$ (GFZ) = -4.6, and  $\Theta$ (USGS) = -4.8. For individual earthquakes,  $\Theta$  may vary between about  $-3.0 > \Theta > 7.0$  (see also Weinstein and Okal, 2005, and Lomax and Michelini, 2009a). The latter authors identified values below -5.7 to be a reliable indicator for very slow tsunami earthquakes.

**Fig. 3.89** Comparison between the  $\Theta = \log(E_s/M_0)$  values calculated as the difference between  $\log E_s(\text{USGS}=\text{GS})$  (upper panel), respectively  $\log E_s(\text{GFZ})$  (lower panel), and  $M_w(\text{GCMT})$  in the magnitude range between 5.5 and 9.0. There is a tendency of decreasing  $\Theta$  with the magnitude of strong and great, mainly subduction zone earthquakes. The different color symbol relate to different types of source mechanism, e.g., upright blue triangles to strike-slip (SS) earthquakes. Note again, as in Figs. 3.85 and 3.86, the much larger data scatter of the USGS data set with its distinct separation of SS earthquakes, which have been corrected for theoretically expected reduced radiation coefficients according to Boatwright and Choy (1986).

$M_w$  has been defined via the  $\log E_s$ - $M_s$  relationship. Following the discussions in Bormann and Di Giacomo (2011), the definition formula for  $M_w$  can be decomposed as follows:

$$M_w = (\log M_0 - \mathbf{A} \text{ const. in the } \log E_s\text{-}M_s \text{ relation} + \mathbf{B} \text{ average } \Theta) / \mathbf{C} \text{ slope of the } \log E_s\text{-}M_s \text{ relation.} \quad (3.149)$$

Since Kanamori (1977) and Hanks and Kanamori (1979) based their  $M_w$  formula on the Richter (1958)  $\log E_s$ - $M_s$  relations with a constant of 4.8 and slope 1.5, and on an assumed average  $\Theta = -4.3$ , they got the  $M_w$  relation, which reads in its standard form of writing

$$M_w = (\log M_0 - 4.8 - 4.3)/1.5 = (\log M_0 - 9.1)/1.5. \quad (3.150)$$

Yet, modern direct  $\log E_s$  determinations and their **orthogonal** regression with the respective event  $M_s(\text{USGS}) = M_{s\_20}$  data (see Fig. 3.87) as well as the average values of  $\Theta$  derived from Fig. 3.89, could not, or only partially, reproduce the constants A to C on which the current  $M_w$  formula is based. For  $\log E_s(\text{GFZ})$  we got according to formula (3.139) and Fig.

3.89 for  $A = 4.51$ , for  $B = -4.6$  and for  $C = 1.51$ . When inserting these constants into the relationship (3.149) we get on the basis of  $\log E_s(\text{GFZ})$  data the new  $M_w$  formula

$$M_w = (\log M_0 - 9.11)/1.51. \quad (3.151)$$

This is very similar with the current standard formula, yielding  $M_w$  values that differ for  $\log M_0$  between about 17 and 23 (i.e.,  $M_w \approx 5.3$  to  $9.3$ ) only within  $-0.04$  and  $-0.07$  m.u.

In contrast, the constants based on the orthogonally regressed  $\log E_s(\text{USGS})$  data according to (3.140) and on the  $\Theta$  values in Fig. 3.89 are  $A = 2.41$ ,  $B = -4.8$ , and  $C = 1.79$ , yielding

$$M_w = (\log M_0 - 7.21)/1.79. \quad (3.152)$$

$M_w$  values calculated via (3.152) with  $\log M_0$  (respectively  $M_w$ ) values as above would differ from those derived with the current  $M_w$  standard formula between  $+0.2$  und  $-0.45$  m.u. Thus, the correctness of the current  $M_w$  formula is essentially confirmed by statistically correct treated GFZ  $E_s$  data, not, however, the respective USGS  $E_s$  data. Interestingly, however, the more heuristically derived relationship  $\log E_s = 1.5 M_s + 4.4$  by Choy and Boatwright (1995) would lead with an average  $\Theta_{\text{USGS}} = -4.8$  from Fig. 3.89, upper diagram, to

$$M_w = (\log M_0 - 9.2)/1.5. \quad (3.153)$$

This is very close to (3.150) and yields  $M_w$  values that are constantly smaller than those derived with the standard formula by only  $0.07$  m.u., i.e., it matches with the latter almost as good as the  $M_w$  formula (3.151) based on regressing  $\log E_s(\text{GFZ})$  over  $M_s(\text{USGS})$ . Thus, we can state, that the current  $M_w$  standard formula is well supported also by modern  $\log E_s$  data, better than the currently used  $M_e$  formula (see the discussion above following the Figs. 3.86 and 3.87).

One should be aware, however, that the large scatter of  $\Theta$  makes global relationships between  $\log E_s$  and  $\log M_0$  often unsuitable for drawing inferences on regional differences in tectonic deformation, stress accumulation and release rates. Furthermore, scaling laws for source parameters derived from low-frequency data, such as  $M_w$  or  $M_0$ , may - with the exception for assessing the tsunami hazard - not be suitable for a realistic assessment of the risk of shaking damage. The latter is mainly caused by frequencies above  $0.3$  Hz, which are, therefore, of greatest interest for earthquake engineers.

Global relations for calculating  $M_0$  via  $M_s$  were published by Ekström and Dziewonski (1988). They plotted more than 2.300 global NEIC PDE  $M_s$  values over Harvard CMT  $\log M_0$  values and calculated for three ranges of  $\log M_0$  the regression relations for  $M_s$  vs.  $\log M_0$ . They read, with  $M_0$  in Nm (**1 Nm = 1 J =  $10^7$  dyn cm =  $10^7$  ergs**) also in all other relations below):

$$M_s = \log M_0 - 12.24 \quad \text{for} \quad M_0 < 3.2 \times 10^{24} \quad (3.154a)$$

$$M_s = -12.24 + \log M_0 - 0.088(\log M_0 - 17.5)^2 \quad \text{for} \quad 3.2 \times 10^{24} \leq M_0 \leq 2.5 \times 10^{26} \quad (3.154b)$$

$$M_s = 0.667 \log M_0 - 6.06 \quad \text{for} \quad M_0 \geq 2.5 \times 10^{26} \quad (3.154c)$$

However, Ekström and Dziewonski (1988) resolved these SR1 relations for  $\log M_0$ , which read with  $M_0$  in Nm

$$\log M_0 = M_s + 12.24 \quad \text{for} \quad M_s < 5.3, \quad (3.155a)$$

$$\log M_0 = 23.20 - (92.45 - 11.40 M_s)^{1/2} \quad \text{for} \quad 5.3 \leq M_s \leq 6.8, \quad (3.155b)$$

$$\log M_0 = 1.5 M_s + 9.14 \quad \text{for} \quad M_s > 6.8. \quad (3.155c)$$

These inverse relations, however, are strictly speaking, not fully correct since the data scatter is significant. Therefore, Ambrasey (1990a) did not recommend their application for moment prediction from  $M_s$  values. Solving (3.155a-c) for  $M_0$  may systematically overestimate moments for larger events and underestimate  $M_0$  for small events. However, Purcaru and Berckhemer (1978 and 1982) derived already earlier for constant strain drop practically the same relationship as in (3.155c), namely  $\log M_0 = 16.1 + 1.5 M_s = 16.1 + 1.5 M_E$ , with  $M_E$  = strain energy magnitude. According to their data plot of  $\log M_0$  over  $M_s$  and  $M_E$ , respectively,  $M_0$  varies for fixed values of  $M_s$  or  $M_E$  within a factor of 6.

Chen and Chen (1989) published detailed global relations of  $M_0$  with  $M_s$ ,  $m_b$  and  $M_l$  in different ranges of magnitudes, respectively seismic moment. These relationships are based on data from about 800 earthquakes in the magnitude range  $0 < M < 8.6$ . These authors also showed that their empirical data are well fit by theoretical scaling relations derived from a modified Haskell model of a rectangular fault which produces displacement spectra with three corner frequencies. Similar global scaling relations had been derived earlier by Geller (1976), also based on the Haskell (1964 and 1966)  $\omega^{-3}$  model. In both papers these relations show saturation, in our opinion too early, for  $M_l$  at about 6.3, for  $m_b$  between about 6.0 and 6.5, and for  $M_s$  between about 8.2 and 8.5 (see introductory discussion in section 3.3.1).

Chen and Chen (1989) derived the following  $\log M_0$ - $M_s$  relationships with a standard deviation of individual values  $\log M_0$  of about  $\pm 0.4$ :

$$\log M_0 = 1.0 M_s + 12.2 \quad \text{for} \quad M_s \leq 6.4, \quad (3.156a)$$

$$\log M_0 = 1.5 M_s + 9.0 \quad \text{for} \quad 6.4 < M_s \leq 7.8, \quad (3.156b)$$

$$\log M_0 = 3.0 M_s - 2.7 \quad \text{for} \quad 7.8 < M_s \leq 8.5, \text{ and} \quad (3.156c)$$

$$\text{with } M_s = 8.5 = \text{const. for } \log M_0 > 22.8 \text{ Nm.} \quad (3.156d)$$

However,  $M_s$ - $M_0$  relations (and vice versa) vary regionally. According to Ambraseys (1990) the global relations (3.155a-c) systematically underestimate  $M_s$  for events in the Alpine region of Europe and adjacent areas by 0.2 magnitude units on average. And Abercrombie (1994) discussed possible reasons for the anomalous high surface-wave magnitudes of continental earthquakes relative to their seismic moment. This illustrates the need for regional scaling of moment-magnitude relationships even in the relatively long-period range.

For  $M_0$  and body-wave magnitudes  $m_b$  (when measured at 1s period) Chen and Chen (1989) give the following global scaling relations (with saturation at  $m_b = 6.5$  for  $\log M_0 > 20.7$ ). Note, however, that this applies only to old  $m_b$  data with amplitude measurement within the first few seconds. IASPEI (2005, 2011 and 2013) standard  $m_b$  saturates in fact only around near 7.5 (see Fig. 3.51 and IS 3.3):

$$\log M_0 = 1.5 m_b + 9.0 \quad \text{for} \quad 3.8 < m_b \leq 5.2, \quad (3.157a)$$

$$\log M_0 = 3 m_b + 1.2 \quad \text{for} \quad 5.2 < m_b \leq 6.5, \quad (3.157b)$$

For the  $M_0$ - $M_L$  relationship for California the same authors assume saturation at  $M_L = 6.3$  at  $\log M_0 > 20.1$  and they approximate the underlying non-linear relationship by three linear relationships in limited magnitude ranges:

$$\log M_0 = M_L + 10.5 \quad \text{for} \quad M_L \leq 3.6, \quad (3.158a)$$

$$\log M_0 = 1.5 M_L + 8.7 \quad \text{for} \quad 3.6 < M_L \leq 5.0, \quad (3.158b)$$

$$\log M_0 = 3 M_L + 1.2 \quad \text{for} \quad 5.0 < M_L \leq 6.3. \quad (3.158c)$$

Average scaling relations among  $m_b$ ,  $M_s$  and  $M_0$  for plate-margin earthquakes have been derived by Nuttli (1985). They yield practically identical values as the equations (3.156a-c) for  $M_0$  when  $M_s$  is known while the deviations are not larger than about a factor of 2 when using  $m_b$  and Eqs. (3.157a and b)) instead.

The need for regional relationships between  $M_0$  and magnitudes is particularly evident for  $M_L$ . When calculating  $M_0$  according to Eqs. (3.157b) and (3.158c) for California and comparing them with the values calculated for a relationship given by Kim et al. (1989) for the Baltic Shield

$$\log M_0 = 1.01 M_L + 9.93 \quad \text{for} \quad 2.0 \leq M_L \leq 5.2 \quad (3.159)$$

we get for  $M_L = 2.0, 4.0$  and  $5.0$ , respectively, values for  $M_0$  which are 3.5, 5.4 and 16.6 times larger for California than for the Baltic Shield. Using instead an even more local relationship for travel paths within the Great Basin of California (Chávez and Priestley, 1985), namely

$$\log M_0 = 1.2 M_L + 10.49 \quad \text{for} \quad 1 \leq M_L \leq 6 \quad (3.160)$$

we get for the same magnitudes even 9, 21 and 32 times larger values for  $M_0$  than for the Baltic Shield according to Eq. (3.159).

Other  $M_0$ - $M_L$  relationships are:

for Southern California (Thatcher & Hanks, 1973):

$$\log M_0 = 1.5 M_L + 9.05 \quad \text{in the range } 3 \leq M_L \leq 7, \quad (3.161)$$

for  $M_L$  from strong-motion records in Greece (Margris & Papazachos):

$$\log M_0 = 1.5 M_L + 9.07 \quad \text{in the range } 3.9 \leq M_L \leq 6.6, \quad (3.162)$$

for Israel (Shapira & Hofstetter, 1993):

$$\log M_0 = 1.3 M_L + 10.0 \quad \text{in the range } 2.2 \leq M_L \leq 5.3, \quad (3.163)$$

for Northwestern Turkey (Parolai et al., 2007):

$$\log M_0 = 1.17 M_l + 10.12 \quad \text{in the range } 0.5 < M_l < 6, \quad (3.164)$$

for the Italian earthquake catalog (Castello et al., 2007):

$$\log M_0 = 1.18 M_l + 10.92 \quad \text{in the range } 3.5 \leq M_l \leq 5.8, \quad (3.165)$$

and for Northwestern Italy (Bindi et al., 2005):

$$\log M_0 = 0.95 M_l + 10.36 \quad \text{in the range } 0 < M_l < 4.5. \quad (3.166)$$

When comparing these various  $\log M_0$ - $M_l$  relationships we realize that the slope for data in the range  $0 < M_l < 7$  tends to increase with  $M_l$  from about 1 to 1.5. Accordingly, the slope for the respective  $M_w$ - $M_l$  relationship varies in this range from about 2/3 to 1 (see Tab. 3.6). The very steep slope in (3.151c), however, is mainly due to the assumption in the related scaling law calculations of a too early saturation of  $M_l$  at 6.3 already.

The slope change, which is in fact a gradual one, is mainly related to the magnitude and stress-drop dependent variability of the seismic source spectra and their corner frequencies in the range of magnitudes considered with respect to the passband of the Wood-Anderson seismometer, whereas the different constants are mainly controlled by regional differences in the attenuation laws (see, e.g., the difference in Tab. 3.6 between the slope 1  $M_w$ - $M_l$  relationships (or slope 1.5  $\log M_0$ - $M_l$  relationships) by Ristau et al. (2005) for crustal and slab earthquakes, respectively, with  $M_l \geq 3.6$  but  $< 6$  in Western Canada). Therefore, in order to avoid physically or regionally wrong conclusions to be drawn from slope differences of various  $\log M_0$  (or  $M_w$ )- $M_l$  relationships it is absolutely necessary to take the magnitude-range of their applicability into account.

While there are plenty relationships for converting  $M_l$ ,  $m_b(\text{old})$  and  $M_s(20)$  data into  $\log M_0$  (or  $M_w$ ), relationships between  $\log M_0$  (respectively  $M_w$ ) and  $m_B$  are very rare. Exceptions are the data plots by Abe (1982) of  $\log M_0$  over classical  $m_B$  for both shallow and deep earthquakes (see Fig. 3.90).

**Fig. 3.90**  $\log M_0$  (in units of  $\text{dyne cm} = 10^{-7} \text{ N m}$ ) versus  $m_B$  for shallow (left diagram) and for intermediate-depth to deep earthquakes (right diagram) according to Figures 1 and 3 of Abe (1982). The apparent stress  $\sigma_a = \mu(E_S/M_0)$  is given in units of  $\text{bar} = 0.1 \text{ MPa}$ . Note that for calculating  $M_0$  and  $C$  for intermediate-depth to deep earthquakes a three times higher rigidity (shear modulus)  $\mu$  of the source medium ( $\mu = 9 \times 10^{11} \text{ dyn/cm}^2$ ) than for shallow earthquakes has been assumed by Abe.

The lines in Fig. 3.90 have been calculated for increment values of  $\sigma_a$  with the relationship

$$\log M_0 = 2.4 m_B - 1.2 - \log(\sigma_a/\mu), \text{ with } M_0 \text{ in N m.} \quad (3.167)$$

This relation results from inserting into the Gutenberg-Richter  $\log E_S$ - $m_B$  relationship (3.134)  $E_S = M_0 \times (\sigma_a/\mu)$  and resolving it for  $\log M_0$ . A line for  $\sigma_a \approx 40 \text{ bar} = 4 \text{ MPa}$ , and thus for a stress drop  $\Delta\sigma \approx 8 \text{ MPa}$ , would be a reasonably good average fit of the data in Fig. 3.90 and correspond for shallow earthquakes with  $\mu = 3 \times 10^{11} \text{ dyn/cm}^2 = 3 \times 10^4 \text{ N m}$  to a relationship

$$\log M_0 = 2.4 m_B + 2.68 \quad (3.168)$$

However, when calculating for shallow earthquakes the linear OSR standard regression through some 974 data pair of GCMT  $\log M_0$  vs.  $m_B(\text{GFZ}) = m_B\text{_{BB}}$ , with the latter measured according to the procedure described by Bormann and Saul (2008), one gets

$$\log M_0 = 1.90 m_B\text{_{BB}} + 6.09, \quad (3.169)$$

and when fitting the same data with a non-linear regression relationship

$$\log M_0 = e^{(-1.103 + 0.375 \text{ mB}_{\text{BB}})} + 14.659. \quad (3.170)$$

All three relationships have been plotted together with the GCMT-GFZ data in Fig. 3.91. One realizes that within the range of the definition by data

- Eq. (3.170) approximates best the relationship between IASPEI standard  $\text{mB}_{\text{BB}}$  and GCMT  $\log M_0$ ;
- all three relationships yield identical average  $\log M_0$  proxy estimates at  $\text{mB} = 6.7$ ;
- other  $\log M_0$  proxy estimates via  $\text{mB}$  differ not more than about 0.5 units from directly measured  $\log M_0$ .

**Fig. 3.91**  $\text{mB}(\text{GFZ}) - \log M_0$  (GCMT) regression models: The exponential model [(Eq. (3.170))] is drawn in purple, the linear OSR model [(Eq. (3.169))] in green and Eq. (3.168), derived by us on the basis of early  $\log M_0$  and classical  $\text{mB}$  data by Abe (1982), as red broken line. The data distribution is shown as color-coded count cells,  $0.1 \times 0.1$  units wide.

Finally, we present in Figs. 3.92 a and b the most recent non-linear regression relationships based on 30,709  $\log M_0$ - $\text{mb}$  as well as 17,472  $\log M_0$ - $M_s$  data of the ISC-GEM Global Instrumental Earthquake Catalog (1900 – 2009). According to Di Giacomo et al. (2013) the respective OSR relationships are

$$\log M_0 = 1.95 \text{ mb} + 7.03, \quad (3.171)$$

$$\log M_0 = 1.00 M_s + 12.30 \quad \text{for } M_s < 6.47, \quad (3.172)$$

and

$$\log M_0 = 1.66 M_s + 7.97 \quad \text{for } M_s > 6.47, \quad (3.173)$$

and the corresponding exponential least-square relationships read

$$\log M_0 = e^{(-4,261 + 0.859 \text{ mb})} + 15.922, \quad (3.174)$$

and

$$\log M_0 = e^{(0,213 + 0.230 M_s)} + 13.28. \quad (3.175)$$

**Fig. 3.92a** mb (ISC - GEM) – log  $M_0$  (GCMT) regression models: The exponential model is drawn in purple and the linear OSR model in green. The data distribution is shown as color-coded count cells  $0.1 \times 0.1$  wide.

**Fig. 3.92b**  $M_s$  (ISC - GEM) – log  $M_0$  (GCMT) regression models: the exponential model is drawn in purple and the bi-linear OSR model in green. The data distribution is shown as color-coded count cells  $0.1 \times 0.1$  wide.

The OSR relationships between log  $M_0$  and  $M_s$ , based on the newest and most homogeneous ISC-GEM Global Instrumental Earthquake Catalogue data set (1900 – 2009) almost perfectly confirms the respective relationships published earlier by Chen and Chen (1989) for  $M_s < 6.4$  [see Eqs. (3.156a)] and of Ekström and Dziewonski (1988) for  $M_s < 5.3$  [Eq. (3.155a)]. The slope of 1.66 in (3.173), however, is larger than the slope of 1.5 in both the Ekström and Dziewonski relationship (3.155c) for  $M_s > 6.8$  and in the Chen and Chen relationship (3.156b) for  $6.4 \leq M_s < 7.8$ . Remember that Kanamori (1977), in his effort to estimate the seismic energy released by strong earthquakes and to develop a non-saturating magnitude scale, calibrated  $M_0$  to  $M_s$  via the Richter (1958)  $\log E_s$ - $M_s$  relationship, knowing about the close relationship between log  $M_0$  and  $M_s$  in the range  $6.5 < M_s < 8$  and assuming a constant average  $E_s/M_0$  ratio (see section 3.2.7.1). Having now plenty of direct  $M_0$  measurements available one could scale them directly to  $M_s$  without the detour over an assumed average  $E_s/M_0$  ratio. This was done by Choy and Boatwright (1995) when developing the energy magnitude scale  $M_e$  by relating directly measured  $E_s$  to  $M_s$  (see section 3.2.7.2). Accordingly, by substituting in (3.173)  $M_s$  by  $M_w$  and resolving it for  $M_w$  one gets

$$M_w = (\log M_0 - 7.97)/1.66. \quad (3.176)$$

When compared with the Kanamori (1977) based IASPEI standard  $M_w$  scale formula (3.68),  $M_w = (\log M_0 - 9.1)/1.5$ , (3.176) would yield for  $\log M_0 = 16$   $M_w = 4.84$  and for  $\log M_0 = 23$

$M_w = 9.05$ , instead of  $M_w = 4.60$  and  $9.27$ , respectively, when using (3.68). Thus the difference between  $M_w$  values calculated with the established and the new formula would be within this range of  $\log M_0$ , approximately corresponding to  $4.5 < M_w < 9.3$ , generally less than 0.25 m.u. This is still a reasonably good agreement but none the less worth considering a change to an  $M_w$  scale that is directly scaled to  $M_s$  for strong earthquakes and not via a  $\log E_S$ - $M_s$  relationship with a constant slope of 1.5 and an assumed constant  $E_S/M_0$  ratio.

The latter is theoretically required when the omega-squared similarity model (as in Fig. 3.5) holds on average. Deviations are then only related to differences in stress drop. Data of Abercrombie (1995) and of the TERRAscope TriNet (Kanamori 2001), however, seemed to indicate that average  $E_S/M_0$  values drop for  $M_w < 5$  below  $10^{-4}$  and even below  $10^{-6}$  for  $M_w < 1$ . However, Oth et al. (2010), analyzing masses of Japanese KiK-net data in the magnitude range  $2.7 \leq M_{JMA} \leq 8$ , could not confirm such an average scale dependence of  $E_S/M_0$  within this range, despite the large individual scatter between about  $4 \times 10^{-4}$  and  $8 \times 10^{-7}$ , which these authors attribute solely to variations in stress drop. Whether this similarity holds down to  $M_w = -4.5$  (Kwiatek et al., 2010), however, and thus the applicability of the standard  $M_w$  formula (3.68) for converting  $M_0$  into moment magnitudes even 11 magnitude units outside the range of its original definition based on  $M_s$  data, seems to be more than questionable.

### 3.3.4 Scaling relations of magnitudes, $M_0$ and $E_S$ with fault parameters (P. Bormann)

Scaling relations of magnitude, seismic moment and energy with fault parameters are used in two ways:

- 1) to get a rough estimate of relevant fault parameter when  $M$ ,  $M_0$  or  $E_S$  of the event are known from the evaluation of instrumental recordings; or
- 2) in order to get a magnitude, moment and/or energy estimates for historic or even prehistoric events for which no recordings are available but for which some fault parameters such as the length of surface rupture and/or amount of surface displacement can still be determined from field evidence.

The latter is particularly important for improved assessment of seismic hazard and for estimating the maximum possible earthquake, especially in areas with long mean recurrence times for strong seismic events. Of particular importance for hazard assessment are also relationships between macroseismic intensity,  $I$ , and magnitude,  $M$ , on the one hand (see Eqs. in 3.2.6.6) and between ground acceleration and  $I$  or  $M$ , on the other hand. Unfortunately, the measured maximum accelerations for equal values of intensity  $I$  scatter in the whole range of  $I = III$  to  $IX$  by about two orders of magnitude (Ambraseys, 1975). The reason for this scatter is many-fold, e.g., human perception is strongest for frequencies around 3 Hz while acceleration and damage might be strongest for more high frequent ground motions. Also, damage depends not only on the peak value of acceleration (PGA) but also depends on its frequency with respect to the natural period of the shaken structures and on the duration of strong ground shaking. Moreover, especially in real-time applications for damage prediction and assessment, peak ground velocity (PGV) data have proven to be much more important than PGA data, especially for mid-rise and high-rise buildings that are typical of modern societies (e.g., Wu et al., 2003). And some structures are particularly vulnerable to large ground displacements and not so much to high accelerations, e.g., pipelines or very long free-spanning bridges.

Relationships between  $M_0$ ,  $M_s$ , and  $E_s$  with various fault parameters are mostly based on model assumptions on the fault geometry, rupture velocity and time history, ambient stress or stress drop, etc. But sometimes these fault parameters can, at least partially, be confirmed or constrained by field evidence or by petrophysical laboratory experiments. As for other scaling relations discussed above, global relationships can give only a rough orientation since the scatter of data is considerable due to regional variability. Whenever possible, regional relationships should be developed.

Sadovsky et al. (1986) found that for both crustal earthquakes and underground explosions the following relationship holds between seismic energy  $E_s$  (in erg) and the seismic source volume  $V_{\text{source}}$  (in  $\text{cm}^3$ ):

$$\log E_s = 3 + \log V_{\text{source}} \quad (3.177)$$

with  $V_{\text{source}}$  for earthquakes being estimated from the linear dimensions of the aftershock zone. This means that the critical energy density for both natural and artificial crustal seismic sources is about equal, roughly  $10^3 \text{ erg/cm}^3$  or  $100 \text{ J/m}^3$ . It does not depend on the energy released by the event.  $E_s$  increases only because of the volume increase of the source. Accordingly, it is not the type of seismic source but the properties of the medium that play the decisive role in the formation of the seismic wave field. However, local and regional differences in ambient stress and related stress drop  $\Delta\sigma \approx 2\mu E_s/M_0$  may modify this conclusion.

Fig. 3.93 shows the relation between seismic moment  $M_0$  and the area  $A_r$  of fault rupture as published by Kanamori and Anderson (1975).  $A_r$  is controlled by the stress drop  $\Delta\sigma$ ; as  $\Delta\sigma$  increases for a given rupture area,  $M_0$  becomes larger. One recognizes that intraplate earthquakes have on average a higher stress drop (around 10 MPa = 100 bars) than interplate events (around 3 MPa). The data in Fig. 3.93 are also well fit by the average relationship suggested by Abe (1975), namely:

$$M_0 = 1.33 \times 10^{15} A_r^{3/2} \quad (3.178)$$

which is nearly identical with the relation by Purcaru and Berckhemer (1982):

$$\log M_0 = (1.5 \pm 0.02) \log A_r + (15.25 \pm 0.05) \quad (3.179)$$

with  $M_0$  in Nm and  $A_r$  in  $\text{km}^2$ . Eq. (3.179) corresponds to the theoretical scaling relation derived by Chen and Chen (1989) for a modified Haskell model with the assumption  $L = 2W$  ( $L$  - length and  $W$  - width of fault rupture,  $A_r = LW = 0.5 L^2$ ) and an average displacement  $\bar{D} = 4.0 \times 10^{-5} L$ . Note that empirical data indicate also other aspect ratios  $L/W$  up to about 30 (e.g., Purcaru and Berckhemer, 1982).

Wells and Coppersmith (1994) gave another relation between moment magnitude and  $A_r$ , derived from a very comprehensive data base of source parameters for historical shallow-focus earthquakes ( $h < 40 \text{ km}$ ) in continental interplate or intraplate environments:

$$M_w = (0.98 \pm 0.03) \log A_r + (4.07 \pm 0.06) \quad (3.180)$$

For the related data see Fig. 3.95b.

**Fig. 3.94** Relation between area of fault rupture  $A_r$  and seismic moment  $M_0$  for inter- and intraplate earthquakes. The solid lines give the respective relationships for different stress drop  $\Delta\sigma$  (in MPa;  $1 \text{ Pa} = 10^{-5} \text{ bars}$ ) (modified from Kanamori and Anderson, Theoretical basis of some empirical relations in seismology, Bull. Seism. Soc. Am., Vol. 65, p. 1077, Fig. 2, 1975; © Seismological Society of America).

**Fig. 3.95** Data plots and regression lines for the relationship between moment magnitude and surface rupture length (left panel), respectively rupture area (right panel), for earthquakes in stable continental regions (SCR) and non-SCR according to Wells and Coppersmith (1994), Bull. Seism. Soc. Am., 54(4), Fig. 17. © Seismological Society of America.

There also exist linear log-log relationships between  $L$  and  $M_0$ . One of such relations, published by Wells and Coppersmith (1994), has been plotted in the left diagram of Fig. 3.95 for earthquakes in stable continental regions (SCR) and non-stable ones. For another average relationship between  $M_w$  and the surface rupture length SRL of strike slip, reverse and normal faulting earthquakes (77 events) these authors give:

$$M_w = 1.16 \log \text{SRL}(\text{km}) + 5.08. \quad (3.181)$$

According to Scholz et al. (1986),  $L$  is for a given seismic moment on average about 6 times larger for interplate (strike-slip) events than for intraplate ones (see Fig. 3.96) and the ratio  $\alpha$  between average fault displacement (slip)  $\bar{D}$  and fault length  $L$ ,  $\alpha \approx 1 \times 10^{-5}$  for interplate and  $\alpha \approx 6 \times 10^{-5}$  for intraplate events. Since this result is independent of the type of fault mechanism, it implies that intraplate faults have a higher frictional strength (and thus stress drop) than plate boundary faults but smaller length for the same seismic moment.

**Fig. 3.96** Fault length  $L$  versus seismic moment  $M_0$  for large inter- and intraplate earthquakes. The solid lines give the respective relationship for the ratio  $\alpha = \bar{D}/L$  (modified from Scholz et al. (1986), Scaling differences between large interplate and intraplate earthquakes, Bull. Seism. Soc. Am., Vol. 76, No. 1, p. 68, Fig. 1; © Seismological Society of America).

The slope of the curves in Fig. 3.96 is 0.5. This corresponds to a relation  $M_0 \sim L^2$  (Scholz 1982; Pegeler and Das, 1996) which is only valid for large earthquakes ( $M >$  about 6.5 to 7). Then the width  $W$  of the fault is already saturated, i.e., has reached its largest extension within the seismogenic zone of brittle fracturing in the crust, respectively lithosphere. Depending on heat flow and composition, the seismogenic zone in the crust is about 10 to 30 km thick. Accordingly, for larger earthquakes, the growth of the fault area with increasing  $M_0$  is in the length direction only.

Recently, there has been some serious debate on the scaling of large earthquakes and their ratio  $\alpha$  (Scholz, 1994a and b and 1997; Romanowicz 1994; Romanowicz and Rundle, 1993 and 1994; Sornette and Sornette, 1994; Wang and Ou, 1998). Romanowicz (1992), who prefers to scale slip not with length but with width, even gives a relationship of  $M_0 \sim L$  in case

of very large earthquakes. In contrast, Hanks (1977) showed that earthquakes with rupture dimensions smaller than the thickness of the seismogenic layer scale according to  $M_0 \sim L^3$  which is equivalent to Eq. (3.177).

Accordingly, in agreement also with a data compilation by Riznichenko (1992), shown in Fig. 3.97, often rather different correlation relationships between source length  $L$ , magnitude  $M$  and energetic class  $K$  have been published by various authors for events in different seismotectonic environments.

**Fig. 3.97** Correlation of source length  $L$  with magnitude  $M$  and energetic class  $K$  according to data from various sources (e.g., curve 1 by Tocher, 1958, curve 2 by Iida, 1959; curve 6 average by Riznichenko, 1992; Russian original 1985). Thin straight lines: related stress drops  $\Delta\sigma$  are given in MPa; broken lines mark the limits of the 68% confidence interval with respect to the average curve 6 (modified from Riznichenko, 1992, Fig. 3; with permission of Springer-Verlag).

Ambraseys (1988) published relationships derived from the dimensions of fault surface ruptures for Eastern Mediterranean and Middle Eastern earthquakes (with  $L$  - observed surface rupture length in km,  $\bar{D}$  - relative fault displacement in cm,  $M_{SC}$  - predicted surface-wave magnitudes):

$$M_{SC} = 1.43 \log L + 4.63 \quad (3.182)$$

and

$$M_{SC} = 0.4 \log (L^{1.58} \bar{D}^2) + 1.1. \quad (3.183)$$

They yield results which are in good agreement with those by Nowroozi (1985) for Iran but they differ significantly from the respective relations given by Tocher (1958) for Western USA and from Iida (1959) for Japan (see curves 1 and 2 in Fig. 3.97).

Khromovskikh (1989) analyzed available data for more than 100 events of different faulting types from different seismotectonic regions of the Earth. He derived 7 different relationships between magnitude  $M$  and the length  $L$  of the rupture zone, amongst them those for the following regions:

a) the Circum-Pacific belt:  $M = (0.96 \pm 0.25) \log L + (5.70 \pm 0.34)$  (3.184)

b) the Alpine fold belt:  $M = (1.09 \pm 0.28) \log L + (5.39 \pm 0.42)$  (3.185)

c) rejuvenated platforms:  $M = (1.25 \pm 0.19) \log L + (5.45 \pm 0.28)$  (3.186)

and compared them with respective relationships of other authors for similar areas.

Other relationships for estimating  $L$  (in km), when  $M_s$  is known, were derived by Chen and Chen (1989) on the basis of their general scaling law using a modified Haskell model for a rectangular fault. These relationships clearly show the effect of width saturation:

$$\log L = M_s/3 - 0.873 \quad \text{for} \quad M_s \leq 6.4 \quad (3.187)$$

$$\log L = M_s/2 - 1.94 \quad \text{for} \quad 6.4 < M_s \leq 7.8 \quad (3.188)$$

$$\log L = M_s - 5.84 \quad \text{for} \quad 7.8 < M_s \leq 8.5. \quad (3.189)$$

The same authors also gave similar relations between the average dislocation  $\bar{D}$  (in m) and  $M_s$ , namely:

$$\log \bar{D} = M_s/3 - 2.271 \quad \text{for} \quad M_s \leq 6.4 \quad (3.190)$$

$$\log \bar{D} = M_s/2 - 3.34 \quad \text{for} \quad 6.4 < M_s \leq 7.8 \quad \text{and} \quad (3.191)$$

$$\log \bar{D} = M_s - 7.24 \quad \text{for} \quad 7.8 < M_s \leq 8.5 \quad (3.192)$$

while Chinnery (1969) derived from still sparse empirical data a linear relation between magnitude  $M$  and  $\log \bar{D}$  (with  $\bar{D}$  in m) for the whole range  $3 < M < 8.5$

$$M = 1.32 \log \bar{D} + 6.27 \quad (3.193)$$

which changes to

$$M = 1.04 \log \bar{D} + 6.96 \quad (3.194)$$

when only large magnitude events are considered.

Probably best established are the relations which Wells and Coppersmith (1994) have determined for shallow-focus (crustal) continental interplate or intraplate earthquakes on the basis of a rather comprehensive data base of historical events. Since most of these relations for strike-slip, reverse and normal faulting events were not statistically different (at a 95% level of significance) their average relations for all slip types are considered to be appropriate

for most applications. Best established are the relationships between moment magnitude  $M_w$  and rupture area [see Eq. (3.174 and Fig. 3.95 right)], surface rupture length (SRL) (see Fig. 3.95 left) and subsurface rupture length (RLD) (both in km). They have the strongest correlations ( $R_{XY} = 0.89$  to  $0.95$ ) and the least data scatter:

$$M_w = (1.16 \pm 0.07) \log (\text{SRL}) + (5.08 \pm 0.10) \quad (3.195)$$

$$M_w = (1.49 \pm 0.04) \log (\text{RLD}) + (4.38 \pm 0.06) \quad (3.196)$$

$$\log (\text{SLR}) = (0.69 \pm 0.04) M_w - (3.22 \pm 0.27) \quad (3.197)$$

$$\log (\text{RLD}) = (0.59 \pm 0.02) M_w - (2.44 \pm 0.11) \quad (3.198)$$

When comparing Eqs. (3.197) and (3.198) it follows that in general the observed surface rupture length is only about 75% of the subsurface rupture length inferred from modeling.

The correlations between  $M_w$  and  $\bar{D}$  as well as  $\bar{D}$  and SLR are somewhat smaller ( $R_{XY} = 0.71$  to  $0.78$ ):

$$M_w = (0.82 \pm 0.10) \log \bar{D} + (6.693 \pm 0.05) \quad (3.199)$$

$$\log \bar{D} = (0.69 \pm 0.08) M_w - (4.80 \pm 0.57) \quad (3.200)$$

$$\log \bar{D} = (0.88 \pm 0.11) \log (\text{SLR}) - (1.43 \pm 0.18) \quad (3.201)$$

$$\log (\text{SLR}) = (0.57 \pm 0.07) \log \bar{D} + (1.61 \pm 0.04). \quad (3.202)$$

Wells and Coppersmith (1994) reasoned that the weaker correlation may reflect the wide range of displacement values for a given rupture length (differences up to a factor 50 in their data set!). These authors also give relations between SLR and the maximum surface displacement which is, on average, twice the observed average surface displacement while the average subsurface slip ranges between the maximum and average surface displacement.

Chen and Chen (1989) also derived from their scaling law the following average values:

- rupture velocity  $v_r = 2.65$  km/s;
- total rupture time  $T_r$  (in s) =  $0.35$  (s/km)  $\times$   $L$  (km); (3.203)
- slip velocity  $dD/dt$  varying between  $2.87$  and  $11.43$  m/s.

However,  $v_r$  and  $dD/dt$  usually vary along the fault during the fracture process. From teleseismic studies we obtain usually only spatially and temporally averaged point source values of fault motion but the actual co-seismic slip is largely controlled by spatial heterogeneities along the fault rupture (see Figs. 3.9-3.12). Large slip velocities over  $10$  m/s suggest very high local stress drop of more than  $10$  MPa (Yomogida and Nakata, 1994). On the other hand, sometimes very slow earthquakes may occur with very large seismic moment but low seismic energy radiation (e.g., "tsunami earthquakes"; Kanamori, 1972; Polet and

Kanamori, 2009). This has special relevance when deriving scaling relations suitable for the prediction of strong ground motions (e.g., Fukushima, 1996).

Scaling relationships between fault parameters, especially between  $D$  and  $L$ , are also controlled by the fault growth history, by age and by whether the event can be considered to be single and rare or composite and frequent (e.g., Dawers et al., 1993; Tumarkin et al., 1994). There exist also scaling relations between fault length and recurrence interval which are of particular relevance for seismic hazard assessment (e.g., Marrett, 1994).

Using Eqs. (3.182), (3.184)-(3.186) and (3.195), one gets for a surface rupture length of 100 km magnitudes  $M = 7.5, 7.7, 7.6, 7.95$  and  $7.4$ , respectively. When knowing the  $M_s$  or  $M_w$  and calculating  $L$  and  $\bar{D}$  according to Eqs. (3.187-3.188), (3.189-3.190), (3.197) and (3.200), one gets for magnitude 7.0  $L = 36$  km and 41 km,  $\bar{D} = 1.4$  m and 1.1 m and for magnitude 8.0  $L = 145$  km and 200 km,  $\bar{D} = 3.8$  m and 5.2 m. The good agreement of the calculated values for magnitudes 7 and the stronger disagreement for magnitudes 8 are obviously due to the growing difference between  $M_s$  (used in the relations by Chen and Chen, 1989) and  $M_w$  (used in the relations by Wells and Coppersmith, 1994) for  $M_s > 7$  (saturation effect). For the rupture duration we get according to Eq. (3.203) for  $M_s = 7$  and 8 and the respective rupture lengths (3.188) and (3.189) approximately 13 s and 51 s, respectively. If we use, however, the empirically derived average rupture duration relation (3.3) according to Bormann and Saul (2009a) the average rupture duration of earthquakes with  $M = 7$  and 8 would be about 25 s and 100 s, respectively.

### 3.4 Determination of fault-plane solutions (P. Bormann and S. Wendt)

#### 3.4.1 Introduction

The direction (polarity) and amplitude of motion of a seismic wave arriving at a distant station depends both on the wave type considered and the position of the station relative to the motion in the earthquake source. This is illustrated by Figs. 3.98a and b.

Fig. 3.98a represents a linear displacement of a point source  $S$  while Fig. 3.98b depicts a right lateral (dextral) shear dislocation along a fault plane  $F$ . Shear dislocations are the most common model to explain earthquake fault ruptures. Note that in the discussion below we consider the source to be a point source with rupture dimension much smaller than the distance to the stations and also much smaller than the wave length considered. First we look into the situation depicted in Fig. 3.98a. When  $S$  moves towards  $\Delta 1$  then this station will observe a *compressional* (+) P-wave arrival (i.e., the first motion is *away* from  $S$ ),  $\Delta 4$  will record a P wave of opposite sign (-), a *dilatation* (i.e., first motion *towards*  $S$ ), and station  $\Delta 2$  will receive no P wave at all. On the other hand, S waves, which are polarized parallel to the displacement of  $S$  and perpendicular to the direction of wave propagation, will be recorded at  $\Delta 2$  but not at  $\Delta 1$  and  $\Delta 4$  while station  $\Delta 3$  will receive both P and S waves.

**Fig. 3.98** Direction of source displacement with respect to seismic stations  $\Delta_i$  for a) a single force at point S and b) a fault rupture F. Note that in the discussion below we consider the source to be a point source with a rupture dimension much smaller than the distance to the stations (Figure by courtesy of M. Baumbach †, 2001).

Somewhat different is the case of a fault rupture (Fig. 3.98b). At stations  $\Delta_1$  and  $\Delta_5$ , which are positioned in the strike direction of the fault, the opposite signs of P motion on both side of the fault will cancel, i.e., no P waves will be observed. The latter also applies for station  $\Delta_3$  which is sited perpendicular to the fault. On the other hand, stations  $\Delta_2$  and  $\Delta_4$ , which are positioned at an angle of  $45^\circ$  with respect to the fault, will record the P-wave motions with maximum amplitudes but opposite sign. This becomes clear also from Fig. 3.100a. It shows the different polarities and the amplitude "lobes" in the four quadrants. The length of the displacement arrows is proportional to the P-wave amplitudes observed in different directions from the fault. Accordingly, by observing the sense of first motions of P waves at many stations at different azimuths with respect to the source it will be possible to deduce a "fault-plane solution". But because of the symmetry of the first-motion patterns, two potential rupture planes, perpendicular to each other, can be constructed. Thus, on the basis of polarity data alone, an ambiguity will remain as to which one was the acting fault plane. This can only be decided either by field evidence on the orientation and nature of seismotectonic faults (see, e.g., Figure 7 and discussion in EX 3.3) or by taking into account additional data on azimuthal amplitude and frequency, respectively wave-form patterns (see Glossary: *directivity*, *directivity focusing*, *directivity pulse*). The latter are due to *Doppler* and constructive wave interference effects caused by the moving and waves radiating source.

In accordance with the above, the amplitude distribution of P waves,  $A_P$ , for a point source with pure double-couple shear mechanism is described in a spherical co-ordinate system  $(\theta, \phi)$  (Aki and Richards, 1980; see Fig. 3.99) by

$$A_P(\theta, \phi) = \cos \phi \sin 2\theta. \quad (3.204)$$

This expression divides the focal sphere into four quadrants. The focal sphere for a seismic point source is conceived of as a sphere of arbitrarily small radius centered on the source. Within each quadrant the sign of the P-wave first motion (polarity) does not change but amplitudes are large in the center of the quadrant and small (or zero) near to (or at) the fault plane and the auxiliary plane, which is perpendicular to the fault plane. The nodal lines for P

waves, on which  $A_p(\theta, \phi) = \cos \phi \sin 2\theta = 0$ , separate the quadrants. They coincide with the horizontal projection of the two orthogonal fault planes traces through the focal sphere. Opposite quadrants have the same polarity, neighboring quadrants different polarities. Note that *compressional first-motion* signals are observed at stations falling into the *tension quadrant* of the source (with tension force directed away from the point source) while *dilatational first-motion signals* are observed at stations falling into the respective *compression quadrant* (with pressure force directed towards the point source).

**Fig. 3.99** Map view of P-wave radiation pattern for a shear fault.  $\theta$  is the azimuth in the plane while  $\phi$  is in fact three-dimensional. See also Fig. 3.98b. Black areas: polarity +, i.e., **upward** P-wave first motion in vertical component records; white areas: -, i.e., **downward** P-wave first motion in vertical component records (modified according to a Figure kindly provided by M. Baumbach †, 2001).

The position of the quadrants on the focal sphere depends on the orientation of the active fault and of the slip direction in space. This is illustrated by Fig. 3.100, which shows the P-wave radiation pattern for a thrust event with some strike-slip component. Thus, the estimation of the P-wave first motion polarities and their back-projection onto the focal sphere allows us to identify the type of focal mechanism of a shear event (termed fault-plane solution). The only problem is that the hypocenter and the seismic ray path from the source to the individual stations must be known. This may be difficult for rays propagating in a heterogeneous Earth with 2-D or even 3-D velocity structure.

**Fig. 3.100** Radiation pattern of the radial displacement component (P wave) due to a double-couple source: a) for a plane of constant azimuth (with lobe amplitudes proportional to  $\sin 2\theta$ ) and b) over a sphere centered on the origin. Plus and minus signs of various sizes denote the alternating amplitude variations (with the spherical coordinates  $\theta$  and  $\phi$ ) of outward (+; extensional quadrant) and inward (-; compressional quadrant) directed motions of the source. The fault plane and auxiliary plane are nodal lines on which  $\cos \phi \sin 2\theta = 0$ . The pair of open arrows in a) at the center denotes the shear dislocation and **P** and **T** in b) mark the penetration points of the pressure and tension axes, respectively, through the focal sphere. (modified from Aki and Richards 1980; with kind permission of the authors).

Fault-plane solutions based on P-wave first motion polarities will be better constrained if additionally the different radiation pattern of S-waves displacement amplitudes is taken into account. In the case of a double-couple mechanism, the S-wave amplitude pattern follows the relationship (see Aki and Richards, 1980)

$$\mathbf{A}_S = \cos 2\theta \cos \phi \boldsymbol{\theta} - \cos \theta \sin \phi \boldsymbol{\phi} \quad (3.205)$$

with  $\boldsymbol{\theta}$  and  $\boldsymbol{\phi}$  - unit vectors in  $\theta$  and  $\phi$  direction,  $\mathbf{A}_S$  - shear-wave displacement vector.

An example is given in Fig. 3.101 for the same fault-plane solution as shown in Fig. 3.100 for P waves. Fig. 3.102 shows the calculated azimuth-dependent vertical component PV, as well as vertically polarized SV and horizontally polarized SH amplitude lobe patterns for two different combinations of **strike, dip and rake** angles of a seismic fault as well as different incidence angles *Incid* of the seismic rays at the station. *Incid* corresponds in the case of a shallow source in a laterally homogeneous 1-D Earth model to the take-off angles of the

considered seismic ray from the source. And Fig. 3.103 shows the P- and S-wave radiation pattern lobes for a local earthquake with respect to the azimuth towards two seismic stations of a local network in Germany and their related records, which show striking differences in their P/S amplitude ratios. For a more general introduction into source directivity and the radiation patterns of earthquake fault mechanisms see section 2.4 in IS 1.1. It provides additional figures plus animations that illustrate the great variability of amplitude radiation and directivity patterns, depending on the controlling fault and rupture parameter combinations.

**Fig. 3.101** Radiation pattern of the transverse displacement component (S wave) due to a double-couple source. a) in the plane  $\{\phi = 0, \phi = \pi\}$  and b) over a sphere centered on the origin. Arrows imposed on each lobe in a) show the direction of particle displacement associated with the lobe while the arrows with varying size and direction in the spherical surface in b) indicate the variation of the transverse motions with  $\theta$  and  $\phi$ . P and T mark the penetration points of the pressure and tension axes, respectively, through the focal sphere. There are no nodal lines as in Fig. 3.100 but only nodal points where there is zero motion. The nodal point for transverse motion at  $(\theta, \phi) = (45^\circ, 0^\circ)$  at T is a maximum in the pattern for longitudinal motion (see Fig.3.100) while the maximum transverse motion (e.g., at  $\theta = 0$ ) occurs on a nodal line for the longitudinal motion. The pair of arrows in a) at the center denotes the shear dislocation (modified from Aki and Richards 1980; with kind permission of the authors).

**Fig. 3.102** Radiation patterns of PV, SV and SH amplitudes for two earthquake ruptures with different fault **dip**, **rake** (= slip direction) and **take-off angle** of the seismic rays at the source (which is in the case of a shallow seismic source in a laterally homogeneous 1-D Earth model equal with the incidence angle **Incid** at the receiving seismic station).

**Fig. 3.103** Comparison of theoretically calculated radiation patterns for an earthquake with well constrained fault plane solution and slip direction with the really observed amplitude ratios between vertical component P and S amplitudes at stations of a local seismic network in Germany. The source depth of the earthquake has been 12.1 km and the epicenter (respectively hypocenter) distances of stations WERN and ROHR were 13.5 km (18.1 km) and 17.5 km (21.3 km).

### 3.4.2 Determination of fault-plane solutions from P-wave polarities

Most fault-plane solutions are still based on P-wave polarity readings only, especially for smaller earthquakes, although a steadily growing number results nowadays from moment tensor solutions via waveform fitting (see Figs. 3.66 and 3.67 as well as IS 3.8, 3.10 and 3.11). Advanced event location and seismogram analysis programs allow plotting of measured polarities on either an equal-angle Wulff net or a Lambert-Schmidt equal area projection (Figs. 3.104; see also Aki and Richards, 1980, Vol. 1, p. 109-110), yet without showing the net grids itself. Then they search for the optimal separation of the quadrants with plus and minus polarities. The quadrants are separated by the two potential fault planes which are, in the assumed idealized rupture model in a homogeneous full-space, perpendicular to each other. As the final result, usually only the black-and-white, or in different colors shaded quadrants of the horizontal 2-D focal-sphere representations, nick-named also as “beach-ball” solutions, are then plotted and presented together with the respective numbers for the strike, dip and rake of the two fault planes. For the basic types of strike-slip, normal and thrust faulting this is shown in Fig. 3.105 and for mixed types of faulting in Fig. 3.106. In the latter figure additionally the poles of the axes of maximum pressure P and maximum tension T have been marked. In this idealized rupture model they are assumed to be situated in the center of the negative and positive polarity quadrants, respectively.

**Fig. 3.104 Left:** Equal angle Wulff net, for which holds  $d = r \cdot \tan(\Theta/2)$  with  $r$  – radius of the net and  $d$  – distance from the network center of a data point with a given azimuth  $AZM$  and take-off angle  $\Theta$ . **Right:** equal area Lambert-Schmidt net with  $d = r \cdot \sin(\Theta/2)$ .

**Fig. 3.105 Left:** “Beach-ball” representations of basic types of faulting together with the respective numbers of strike, dip and rake angle for the respective fault plane and auxiliary plane, which is a potential fault plane as well. **Right:** Cartoons of the related motions of crustal blocks. Note that a pure strike-slip rupture may occur also on a fault that does not dip vertically and reverse and normal ruptures on planes with other dips than 45 degrees. Moreover, especially for ruptures near to the Earth surface the complementary fault planes may in reality not intersect at a right angle (e.g., by steepening of the dip of bended listric faults towards the surface). See also discussion under 3.1.2.6.

**Fig. 3.106** “Beach-ball” presentation of the net projections of the fault plane **cut-traces**, the quadrants of different polarities, and of the penetration points (poles) of the P- and T-axes through the **lower focal hemisphere** for different faulting mechanisms. White sectors correspond to negative and black sectors to positive P-wave first-motion polarities. Note that mixed types of faulting occur when the rake angle  $\lambda \neq 0, 180^\circ$  or  $\pm 90^\circ$ , e.g., in the case of normal faulting with a strike-slip component or strike-slip with a thrust component. Also, dip angles  $\delta$  may vary between  $0^\circ < \delta \leq 90^\circ$  (modified Figure after M. Baumbach †, 2001).

Two important terms, printed in bold letters in Fig. 3.106, have to be explained, namely the notions **cut-trace** and **lower focal hemisphere**. Our problem is that the fault plane cuts through a conceived 3-D “focal sphere”, which can be separated into an upper and a lower one. All cut traces of the fault through the focal sphere are great circles. In order to reconstruct the orientation of the fault plane in space and to measure its strike, dip and rake angles in a 2-D

stereoscopic net we have to project the great circle cut trace of the fault through the focal sphere onto the horizontally placed net. The degree of bending of the projected cut traces depends on the fault dip. Vertically dipping faults are represented by straight lines running through the center of the net, whereas half-circles along the perimeter of the net represent a horizontal fault. However, from Fig. 3.107 we realize that a single fault would yield two such cut-trace projections, one resulting from the cut through the upper hemisphere and the other from the cut through the lower hemisphere. These two traces are mirrored on the strike direction of the fault, resulting in an  $180^\circ$  ambiguity. To avoid this, one has first to make up one's mind which data should be projected to the horizontal diagram, those related to the lower hemisphere or to the upper hemisphere. This, however, depends on the distance range of observation. In the local range, the P-wave first motion will usually be related to  $P_g$ , which has left the source upward through the upper focal hemisphere. However, stations at distances larger than about 150 to 250 km will record  $P_n$  as the first P-wave, which has left the source through the lower focal hemisphere. The same applies to all teleseismic P-wave rays. However, with EX 3.2 we demonstrate that even in the local distance range, considering only records at distances less than 50 km, the first arriving P-wave first may already be a critically refracted P at a pronounced velocity discontinuity in the upper crust and thus of a head-wave type as  $P_n$  which has left the lower focal hemisphere. If one then wishes to make use of the data of both upper and lower hemisphere rays in order to have a better azimuth and take-off angle distribution of data in the diagram then one has to correct the data from the non-priority hemisphere accordingly. How the corrections of the take-off angles and azimuths of the “wrong” hemisphere rays have to be calculated is illustrated with Figures 1 and 2 of EX 3.2.

Although black-box computed fault-plane solutions are very comfortable, they are educationally not very revealing about how the procedure really works, on which assumptions it is based and how accurate the fault-plane solutions are. In order to get at least a feeling for it as well as an appreciation for the cumbersome tedious work accomplished by the early “fathers” of systematic investigations of fault-plane solutions and their relationships to seismotectonics, one should have done oneself at least once a few fault-plane solutions manually. We outline in the following the basic principles and provide with EX 3.2 an exercise with detailed step-by-step guidance, solutions and discussions.

A good seismogram analysis software, used for phase onset and polarity picking as well as the event location, can produce as a spin-off output also a file with the following data (see, e.g., Table 1 in EX 3.2): Station code, epicenter distance, azimuth AZM of the station with respect to the source, take-off angle  $\Theta$  of the seismic ray from the source, and the P-wave first motion polarities + (or U = upward motion in the record) or – (or D = downward motion in the record). These polarities have to be plotted on either the Wulff or the Lambert net at the correct position for the given AZM and  $\Theta$  of seismic ray towards the station (as shown in Fig. 3.104, left side, for one observation in the Wulff net). Principally, both the Wulff net and the Lambert net projections yield quantitatively the same results. The latter, however, has the advantage that it provides visually a less cluttered plot of data with take-off angles less than  $45^\circ$ .

As a first step we should pin a transparent sheet with a needle to the net center and mark the N, E, S, and W direction as well as the network perimeter on the transparent sheet. Next we transfer all data points according to their AZM and  $\Theta$  values on the transparent sheet (shown in gray on Fig. 3.108a) and mark them there with their respective polarities in an unambiguous signature. Then the transparent sheet should be rotated over the net center until one finds on the underlying net a great circle meridian which separates best the + and – signs (or related symbols as in Fig. 3.108). By clockwise rotation, we find in our demonstration example a meridian on the left side which separates well the compressional first motions from the dilatational ones. This great circle trace should be drawn with a marker pen on the transparent sheet and termed fault plane one = FP1 (red in Fig. 3.108b).

Next we search for the complementary second (or auxiliary) fault plane trace FP2, remembering that it should be situated  $90^\circ$  apart from FP1 in the case of rupture in a homogeneous full-space. Therefore, we should mark on the transparent sheet the pole P1 of FP1, through which FP2 has to go. P1 is perpendicular from the middle of FP1,  $90^\circ$  away towards the right (red dot in Fig. 3.108b). By counter clockwise back rotation of the transparent sheet we find then indeed another great circle, marked in blue in Fig. 3.108c, which goes through P1 and separates at least the majority of black dots from the majority of the open circles on the right side. FP1 and FP2 cross each other in the lower part of the net at an angle of  $90^\circ$ . Accordingly, the pole P2 of FP2 would be placed on FP1,  $90^\circ$  upwards from this crossing point of the two fault planes. Note that all angles have to be measured on great circles.

You will realize that sometimes polarities + and – are rather close to each other, respectively very close to the fault plane trace which is supposed to separate them. As in Fig. 3.108c, we might even find some polarities to be on apparently the wrong side of the fault, in the wrong quadrant. This, however, is unavoidable. We should remember that a fault plane is a nodal line for P waves (see Fig. 3.100), along which P-wave amplitudes vanish or are very small. Accordingly, if recorded at all, they have a very low signal-to-noise ratio. This may result in

wrong reading of the polarity of the usually weaker first half swing. Therefore, nearby placed opposite polarities in the data plot are even “strategic points” to look for, because they are likely to be situated close to the nodal lines. This is also illustrated below by one example from EX 3.2 (Fig. 3.109). In fact, computer programs for finding the optimal fault-plane cut traces through polarity plots aim at minimizing both their distance from conflicting polarity clusters as well as of the number of wrong polarities in the respective quadrants.

**Fig. 3.108** Illustration of the first essential steps when manually searching for the two fault plane traces that associate at least the majority of read polarities correctly with compressional and dilatational quadrants. FP1 = fault plane 1, FP2 = auxiliary second fault plane, P1= pole of FP1. Modified and amended from Andresen (Fault plane solutions <http://www.learninggeoscience.net/free/00071>).

**Fig. 3.109** Example for another data set from EX 3.2 to illustrate how FP1 has been found as an appropriate great circle which passes through two clusters of nearby switching polarities, (see blue arrows) and at the same time separating well the majority of + and – (green dots) first motions in the upper part of the data plot. Shown is also how to find the pole P1 and how to measure the dip and the strike of FP1.

In summary, for obtaining a fault-plane solution, basically three steps are required:

- (1) Calculating the positions of the penetration points of the seismic rays through the focal sphere which are defined by the ray azimuth AZM and the take-off (incidence) angle  $\Theta$  of the ray from the source.
- (2) Marking these penetration points through the upper or lower hemisphere in a horizontal projection of that sphere using different symbols for compressional and dilatational first arrivals. Usually, lower hemisphere projections are used. Rays which have left the upper hemisphere have then to be transformed into their equivalent lower hemisphere ray. This is possible because of spherical symmetry of the radiation pattern (see Fig. 3.100).
- (3) Partitioning the projection of the lower focal sphere by two perpendicular great circles which separate all (or at least most) of the + and - arrivals in different quadrants.

When moving back the marked N direction on the transparent overlay sheet in Fig. 3.108c to the north direction of the stereographic net then we get the beach-ball fault-plan solution depicted in Fig. 3.110. And Fig. 3.111 shows, how the strike, dip, and rake (slip) angles of the two potentially acting faults FP1 and FP2 as well as the azimuth and plunge angles of the pressure and tension axes P and T can then be read on the net diagram. P and T are situated on the equatorial plane EP midway between FP1 and FP2. For more details and how one can decide by way of field evidence, which of the two calculated fault planes has likely be the acting one, see EX 3.2.

**Fig. 3.110 Left:** Polarity data plot in a Lambert-Schmidt net with black dots representing compressional P-wave first arrivals and open circles dilatational signals, respectively; **Right:** the “beach-ball” fault-plane solution deduced from this polarity pattern. It represents a normal faulting with a small strike-slip component along a NNW, respectively SSE striking fault.

**Fig. 3.111** Determination of the fault plane parameters  $\phi$ ,  $\delta$  and  $\lambda$  in the net diagram. The polarity distribution, slip direction and projection of FP1 in this diagram corresponds qualitatively to the faulting case depicted in Fig. 3.107 upper right, namely to a thrust earthquake with a strike-slip component. For abbreviations used see text. **Note:**  $\lambda^* = 180^\circ - \lambda$  when the center of the net lies in the tension (+) quadrant (i.e., event with thrust component) or  $\lambda^* = -\lambda$  when the center of the net lies in the pressure quadrant (i.e., event with normal faulting component). P1, P2 and P3 mark the positions of the poles of the planes FP1 (fault plane), FP2 (auxiliary plane) and EP (equatorial plane) in their net projections. All three planes are perpendicular to each other and intersect in the poles of the respective third plane, i.e., FP1 and FP2 in P3, FP1 and EP in P2 etc. **P** and **T** are the penetration points (poles) of the pressure and tension axes, respectively, through the focal sphere. + and – signs mark the quadrants with compressional and dilatational P-wave first motions.

For quick proper understanding of published beach-ball solutions, one should just remember a few “rules of thumb”, which are well documented by Fig. 3.106:

Note that on the basis of polarity readings alone it cannot be decided whether FP1 or FP2 was the active fault.

- If the two potential fault planes cross each other within the beach ball or net, then there is some strike-slip component involved;
- In the case of pure strike-slip the two fault traces cross as straight lines in the center of the net, respectively the beach-ball;
- If this center is situated in a dilatation or in a compression quadrant then there is a normal faulting, respectively a thrust faulting component involved;

- In the case of pure normal or thrust faulting, either the P axis or the T axis is placed in the net or beach-ball center and the two fault planes do not cross each other within the perimeter (see Fig. 3.106);
- For proper determination of the strike directions of the two faults think yourself standing in the net center with the FP1 fault trace towards your right-hand side. Then look forward along the fault trace until it meets the perimeter. The strike direction of FP1 is then the angle clockwise from north which you read on the perimeter of the net. For finding  $\phi(\text{FP2})$  you have to turn around at the net center so as to place now FP2 at your right-hand side, and then look again towards the end point of FP2 on the perimeter. For the fault-plane solution in Fig. 3.111 you thus get  $\phi(\text{FP1}) = 30^\circ$  and  $\phi(\text{FP2}) = 157^\circ$ ;
- On the basis of polarity readings alone it cannot be decided whether FP1 or FP2 was the active fault.

However, discrimination from seismological data alone is still possible but requires additional study of the *directivity effects* such as azimuthal variation of frequency (*Doppler effect*), amplitudes and/or waveforms (see, e.g., Fig. 3.112 and related discussions and figures in Lay and Wallace, 1995, and in section 2.4 in IS 1.1). For sufficiently large shocks these effects can more easily be studied in low-frequency teleseismic recordings while in the local distance range, high-frequency waveforms and amplitudes may be strongly influenced by resonance effects due to near-surface low-velocity layers (see Chapter 14).

**Fig. 3.112** Example for an amplitude directivity effects: Variability of P- and SH-wave amplitude for a fault rupture propagating unilaterally from left to right with a ratio between rupture and shear wave velocity  $v_r/v_s = 0.5$  (left column) and  $v_r/v_s = 0.9$  (right column), respectively. (From Kasahara, 1981; © Cambridge University Press).

Moreover, seismotectonic considerations or field evidence from surface rupture in the case of strong shallow earthquakes may also allow to resolve this ambiguity (see EX 3.2, Figure 7 and related discussion).

Finally, we present with Fig. 3.113 an example for the fault-plane solution derived for a local earthquake in the Vogtland swarm earthquake region in Germany by means of polarity readings. One can nicely associate the positive first-motion polarity traces (in red) and the respective negative record traces (in blue and turquoise) with the related + and – quadrants of the fault-plane solution plotted over the epicenter of this earthquake.

**Fig. 3.113** Vertical component recordings of Pg first arrivals at seismic stations in Germany from a local earthquake at epicentre distances between 10 km and 55 km in different azimuths and the „beach ball“ fault-plane solution derived from first motion polarities plotted over the epicenter. The acting fault plane had a strike of about 150° north. It was a normal faulting rupture with a left-lateral strike-slip component.

### 3.4.3 Accuracy of fault-plane solutions

Fault planes determined by eye-fit to the polarity data may be uncertain by about  $\pm 10^\circ$ . This is acceptable. Even computer assisted best fits to the data will produce different acceptable solutions within about the same error range with only slightly different standard deviations (e.g., Figure 3.114 with NEIC and HRVD solutions, respectively).

**Figure 3.114** Typical section of an ISC bulletin (left) with NEIC (USGS National Earthquake Information Center) and Harvard University (HRVD) moment-tensor fault-plane solutions (right) for the Italy deep earthquake (h = 286 km) of Jan. 05, 1994. Columns 3 to 5 of the bulletin give the following data: 3 - epicentral distance in degrees, 4 - azimuth AZM in degrees, 5 - phase code and polarity.

In addition, one has to be aware that different fitting algorithm or error-minimization procedures may produce different results within this range of uncertainty for the same data. A poor distribution of seismograph stations (resulting in insufficient polarity data for the net diagram), erroneous polarity readings and differences in model assumptions (e.g., in the velocity models used) may result in still larger deviations between the model solutions and the actual fault planes. One should also be aware that the assumed constant angular ( $45^\circ$ ) relationship between the fault plane on the one hand and the pressure and tension axis on the other hand is true in fact only in the case of a fresh rupture in a homogeneous isotropic full-space without internal friction. It may not be correct in the stress environment of real tectonic situations with prefractured rock, distinct anisotropic rock fabric and internal friction. Then **P** and **T**  $\neq \sigma_1$  and  $-\sigma_3$ , respectively, is likely (see dynamics of faulting by Anderson, 1951, and discussion in section 3.1.2.6: *Parameters which describe and control the source mechanism*).

### 3.4.4 Computer-assisted fault-plane solutions (P. Bormann)

There exist quite a number of computer programs for the determination of both single and joint fault-plane solutions from first-motion data (e.g., Brillinger et al., 1980; Bufo and Udías, 1984; Udías and Bufo, 1988, and others referred to below). In most applications for local earthquakes homogeneous flat-layered velocity models are acceptable, i.e., layers with constant velocities and velocity discontinuities at the boundaries. The majority of location programs (e.g., HYPO71 by Lee and Lahr, 1975; HYPOELLIPSE by Lahr, 1989 and 2003; HYPOINVERSE by Klein, 1978, 1985 and 2002) are based on this type of velocity model. However, HYPOINVERSE and HYPOELLIPSE do also accept layers with linear velocity gradients. Moreover, HYPOELLIPSE may locate local events with predefined travel-time tables, too. During the location procedure the ray paths to the stations are calculated. The azimuth AZM and the take-off angle  $\Theta$  at which the P wave, arriving at a given station, leaves the focal sphere are listed in the output files. The remaining problem to be solved is to find the distribution of P-polarities on the focal sphere and to estimate the angles describing the focal mechanism.

The computer program FPFIT (Reasenberger and Oppenheimer, 1985) calculates double-couple fault-plane solutions based on P-wave polarity readings. It accepts as input the output files of the localization programs HYPO71, HYPOELLIPSE and HYPOINVERSE. The inversion is accomplished through a grid-search procedure that finds the source model by *minimizing a normalized weighted sum of first-motion polarity discrepancies*. Two weighting factors are incorporated in the minimization. One of them reflects the estimated variance of the data while the other one is based on the absolute value of the P-wave radiation amplitude. In addition to the minimum-misfit solution, FPFIT finds alternative solutions corresponding to significant relative misfit minima. The existence of several minima may be due to insufficient number of polarity readings, localization errors, polarity misreadings or an inadequate velocity model (e.g., not modeled refractions) resulting in an incorrect position of the P-wave first-motion polarities on the focal sphere. One has also to be aware that it sometimes may happen that the seismometer component outputs have been wrongly plugged at a given station, resulting in systematically wrong polarity readings by such a station. In the case of models which perfectly fit the data, FPFIT applies an additional constraint. Its effect is to maximize the distance sum between the observation points and the nodal planes on the focal sphere. The display program FPLOT shows the final fault-plane solution and the estimated uncertainty in terms of the range of possible orientations of the pressure and tension axes which is consistent with the data. This USGS software for Unix and Linux platforms is also available from the ORFEUS Software Library.

While the above programs accept only the output files of the hypocenter localization programs for local events, another widely used program package for seismogram analysis, SEISAN (Havskov, 1996; Havskov and Ottemöller, 1999) uses a modified version of the program HYPOCENTER (Lienert et al., 1988; Lienert, 1991; Lienert and Havskov, 1995). Its version 9.2 can be downloaded via the link *Download programs and files* on the front page or directly via <http://folk.uib.no/lot081/seisan.html>. The main modifications are that it can also accept secondary phases and locate teleseismic events. The output files are used in conjunction with the programs FOCMEC (Snoke et al., 1984; current version 2008 can be downloaded from the IRIS software library), FPFIT and HASH (see below) for the determination of the fault plane parameters by using both P-wave first-motion polarities and P/S amplitude ratios, both in the local, regional and teleseismic distance range.

In the case of sparse networks or weak events, the number of polarity data may be too small and/or their distribution in distance and azimuth not appropriate for reliable estimation of fault-plane solutions on the basis of P-wave polarity readings alone. In this case P-, SV- and SH-amplitudes can be used in addition to polarities in order to get more stable and better constrained, i.e., less ambiguous fault-plane solutions. This is due to the difference in the azimuth and take-off angle dependent P-wave and S-wave polarity and amplitude patterns for a given source mechanism (see Figs. 3.100 – 3.103). Fig. 3.115 illustrates this for a teleseismic deep earthquake.

**Fig. 3.115 a)** Vertical component P and S-wave records from a deep earthquake near Japan (28 Sept. 2007, mb(PDE) = 6.7, h = 260 km). The three stations have similar epicentral distances ( $\Delta = 54 - 58^\circ$ ) and all recorded a compressional P-wave first motion. This does not tell much about the source mechanism, in contrast to the S/P amplitude ratio which strongly differs with azimuth Az.

**b)** The fault-plane solutions FPS obtained for this earthquake. **Left:** The FPS derived from the Harvard moment tensor inversion, here plotted together with 13 available P-wave polarity readings which all fall within one quadrant. **Middle:** Completely inconsistent possible FPSs obtained by a grid search for the 13 polarity readings, all but one being compressional. P and T are the related possible pressure and tension axes **Right:** FPSs obtained by using the 13 polarities and 5 amplitude ratios from 3 stations. Triangle is dilation, hexagon compression and H and V indicate horizontal and vertical component amplitude ratios. Copied with kind agreement of the authors from Havskov and Ottemöller (2010); © Springer Publishers.

The program FOCMEC allows to calculate best fitting double-couple fault-plane solutions from P, SH and SV polarities and/or SV/P, SH/P or SV/SH amplitude ratios provided that the ratios are corrected to the focal sphere by taking into account geometrical spreading, attenuation and free-surface effects. For surface correction the program FREESURF, which is supplied together with FOCMEC, can be used. The applied Q-model has to be specified according to the regional attenuation conditions or related corrections. When adopting a constant  $V_P/V_S$  velocity ratio, the geometrical spreading is the same for P and S waves and absolute changes in amplitude cancel each other in the above amplitude ratios. Head waves and amplitude changes at velocity boundaries require special treatment. The solution is obtained by grid search over strike, dip and slip of the double-couple source. The program FOCPLT, also provided together with FOCMEC, allows to plot upper or lower hemisphere projections of the focal sphere and to show the data, i.e., the fault planes, together with the poles of the pressure (P) and tension (T) axes for SH and SV waves. Note that S-wave amplitudes are zero in the direction of P and T.

A more recent USGS program is HASH 1.0 for Unix platforms. It also computes double-couple earthquake focal mechanisms from both P-wave first motion polarities and, optionally S/P amplitude ratios.

FMSI is a program developed by Gephart (1990). It is a focal mechanism stress inversion package using earthquake focal mechanisms and fault/slickenside data. Kikuchi and Kanamori (1982 and 1986) developed a program for teleseismic body-wave inversion aimed at deriving information about the fault kinematics and/or fault mechanics, and Another program for interactive moment tensor retrieval, termed ISOLA-GUI (Authors: Jiri Zahradnik and Efthimios Sokos) can be downloaded via [seismo.geology.upatras.gr/isola/](http://seismo.geology.upatras.gr/isola/).

Other important software tools are presented in the International Handbook on Earthquake and Engineering Seismology (Lee et al., 2003) (TDMT\_INVC, Time Domain Seismic Moment Tensor Inversion Code by Douglas Dreger; [ftp://www.orfeus-eu.org/pub/software/iaspei2003/8511.html](http://ftp://www.orfeus-eu.org/pub/software/iaspei2003/8511.html)) and in “Computer Programs in Seismology” (Charles J. Ammon and George Randall; regional moment tensor inversion set of programs; <http://www.eas.slu.edu/eqc/eqccps.html>). For more information and links to programs consult the ORFEUS Software Library (<http://www.orfeus-eu.org/Softwarelib.html>) and IRIS (<http://www.iris.washington.edu>).

### **3.4.5 Estimating $M_0$ , the size of rupture area, average slip and stress-drop from measured seismic spectra (P. Bormann)**

Besides deriving some rough estimates of the point source type of rupture, i.e., of the fault-plane solution and average slip direction by analyzing the azimuthal direction of P-wave first motion polarities and/or S/P amplitude ratios additional information about the seismic moment, the size of the rupture area, the average slip and stress drop can be derived by analyzing the seismic spectra of the recorded P and/or S waves. However, with reference to the discussions in section 3.3.1 on seismic scaling laws one should be aware that all these inferences on not directly measurable source parameters are model-based and none of the available models can correctly account for all the parameter and rupture complexities in the real inhomogeneous Earth lithosphere. Therefore, all calculations aimed at deriving these additional parameter informations, have to make assumptions. We shortly demonstrate this

here by way of example, also with reference to the related exercise EX 3.4 and the conclusions drawn from it.

With reference to Fig. 3.5 and to formulas (3.1) and (3.2) the scalar seismic moment is written

$$M_0 = \mu \bar{D} A = 4\pi d \rho v_{p,s}^3 u_0 / R_{\theta,\varphi}^{p,s} \quad (3.206)$$

and thus can be calculated when measuring the spectral displacement plateau amplitude  $u_0$  of the radiated seismic source spectrum. However, this is not directly available, but is available only via the spectra recorded at some distance and specific azimuth away from the source. Therefore, in order to get a reasonable realistic estimate of the primary source spectrum one has to correct it for wave propagation and source radiation effects. This, however, requires either reliable knowledge or good average model assumptions about the

- hypocenter distance  $d$  of the source;
- distribution of density  $\rho$  and of the P- or S-wave velocity  $v_p$  or  $v_s$  in the more or less inhomogenous Earth;
- frequency-dependent intrinsic and scattering attenuation of the recorded wave amplitudes for correcting the measured spectral amplitudes;
- surface amplification factor that depends on the incidence angle of the considered seismic wave at the recording station and which is in fact again frequency dependent (see Fig. 2.7 in Chapter 2);
- source radiation coefficient  $R$  with respect to the seismic ray recorded at the given seismic station, which is different for P and S waves and depends on the take-off angle and azimuth under which considered seismic ray has left the source.

It is obvious, that most of these factors are only roughly known and that some of the errors, e.g. in the velocity model, propagate even with the third power (Eq. (3.200)).

Additionally, the recorded waveforms of well defined non-dispersive seismic body phases have a limited duration of only a few seconds for near earthquakes, up to a few minutes at best for very strong teleseismic events. This limits the spectral range that can be analyzed and makes the recorded spectra rather noisy (see Fig. 3.116). This limits in turn also the accuracy with which  $u_0$  and the corner frequency  $f_c$  can be measured on real spectra.  $f_c$  is related to the geometric size of the rupture and instrumental for calculating either the radius of assumed circular ruptures (usually for smaller sources) or via even more vaguely estimated additional corner frequencies in the sloping part of the spectrum also of the width  $W$  and length  $L$  of the rupture plane of larger earthquakes. Knowing either  $R$  or  $L$  plus  $W$ , one may roughly estimate the rupture area via the relationship

$$f_c = c_{m1} v_{p,s} / \pi R = c_{m2} v_{p,s} / (L \times W)^{1/2} \quad (3.207)$$

with  $c_{m1}$  and  $c_{m2}$  being model-dependent constants. Via (3.201) one can relate  $f_c$  to a critical wavelength  $\lambda_c$  which is in the order of the source diameter or the sqr of the product  $L \times W$ :

$$\lambda_c = v_{p,s} / f_c = c_{m3} \pi R = c_{m4} (L \times W)^{1/2}. \quad (3.208)$$

Again,  $c_{m3}$  and  $c_{m4}$  are other model-dependent parameters.

**Fig. 3.116** Vertical component record of an Erzincan, Turkey, earthquake aftershock. For the indicated P-wave window the source spectrum on the right side, corrected for instrument response, source distance and attenuation, has been calculated. **Note:** The apparent strong increase of noise amplitudes for  $f > 30$  Hz is sampling noise due to the steep anti-alias filter roll-off for higher frequencies.

With EX 3.4 we show that even for identical measurement input parameters  $u_0$  and  $f_c$ , which are both already afflicted with model and reading errors, the calculated values for  $R$ ,  $A$ , average displacement  $\bar{D}$  via Eq. (3.200), and stress drop via the formula  $\Delta\sigma = (7/16) M_0 / R^3$  according to Eshelby (1957) and Keilis-Borok (1959), may already differ by a factor of about 1.8, 3, 4 and 6, respectively, depending on whether one calculates them either according to the Brune (1970, 1971) or to the two Madariaga (1976) models, which all assume a circular rupture. This means, however, that one has to use all such model-derived parameters with great caution and accept that they cannot be accurate in absolute terms. Nevertheless, they may be useful, especially when comparing relative parameter changes in space and time in certain seismotectonic areas, or, e.g., for specific aftershock sequences or earthquake swarms. And if in future for the given area better models are available then one may have a chance also to re-calibrate earlier data with the hope to improve also their accuracy in absolute terms.

## Comments and Acknowledgments

The new Chapter 3 is a strongly revised and largely expanded version of Chapter 3 in the NMSOP-1 editions of 2002 and 2009. Two of the former co-authors (M. Baumbach and G. Bock) have regrettably passed away already at much too young an age. We have kept and acknowledged some of the figures by M. Baumbach in the current Chapter and moved others in the related exercise EX 3.2 by Bormann, Baumbach and Wendt. The former sub-chapter of G. Bock has now the status of an independent Information Sheet (IS 3.8), thus being a lasting memory to Günther's major contribution to NMSOP-1. Also, the original sub-chapter on seismic energy determination by G. Choy has become an independent IS 3.6, complemented already by IS 3.5 and awaiting another committed IS 3.10 on seismic energy determination from local and regional seismic events, in collaboration with J. L. Boatwright. Thus, the upgrading and complementation of these important and rapidly developing modern topics have been made independent on the future availability of the editor and main author of Chapter 3. In concordance with this G. Bock's IS 3.8 has also been upgraded and

complemented by a new information sheet IS 3.9 on seismic moment tensor solutions in the local, regional and teleseismic range and by a practical, EX 3.6, on seismic moment tensor inversions using the KIWI tools (with downloadable data and software). All these new or still forthcoming complementary IS should be considered as being integral parts of Chapter 3.

The current finally reviewed and revised version of Chapter 3 replaces the earlier pre-review publication on the Internet. The authors owe greatest thanks to J. W. Dewey of the USGS, co-chairman of the IASPEI/CoSOI Working Group on Magnitude Measurements, for his painstakingly careful and constructive review of the whole Chapter. We have greatly benefitted from his comments, recommendations, corrections and hints to missing items. For several more partial reviews, editorial changes and additional contributions, some made in terms of complementary figures, the editor owes great thanks to J. Dewey, G. Choy, J. Havskov, G. Nolet, A. Lomax, A. Michelini, P. Gasperini, B. Lolli and L. Ottemöller. Quite many figures have also been contributed by J. Saul of the GFZ German Research Centre for Geosciences. They are based on collaborative work and joint journal publications with P. Bormann as well as on a joint presentation with P. Bormann and S. Wendt at the 2012 General Assembly of the European Seismological Commission. All contributed figures by non-authors have been separately acknowledged in the respective sections and captions.

## 1 Local magnitude $M_L$

The classical formula for determining the local magnitude  $M_L$  is, according to Richter (1935),

$$M_L = \log A_{\max} - \log A_0 \quad (1)$$

with  $A_{\max}$  in mm of measured zero-to-peak trace amplitude in a Wood-Anderson seismogram. The respective corrections or calibration values  $-\log A_0$  are given in Table 1 as a function of epicentral distance  $\Delta$ .

**Table 1** The classical tabulated calibration function  $-\log A_0(\Delta)$  for local magnitudes  $M_L$  according to Richter (1958).  $A_0$  are the trace amplitudes in **mm** recorded by a Wood-Anderson Standard Torsion Seismometer from an earthquake of  $M_L = 0$ .

| $\Delta$ (km) | $-\log A_0$ | $\Delta$ (km) | $-\log A_0$ | $\Delta$ (km) | $-\log A_0$ | $\Delta$ (km) | $-\log A_0$ |

| 60            | 2.8         | 200           | 3.5         | 380           | 4.4         | 560           | 4.9         |
| 70            | 2.8         | 220           | 3.65        | 400           | 4.5         | 580           | 4.9         |
| 80            | 2.9         | 240           | 3.7         | 420           | 4.5         | 600           | 4.9         |

Different from the above, the *IASPEI Working Group on Magnitude Measurement* now recommends, as approved by the IASPEI Commission on Seismic Observation and Interpretation (CoSOI), the following standard formula for calculating  $M_L$  (**quote from IASPEI, 2011, which uses the nomenclature ‘ $ML$ ’ instead of ‘ $M_L$ ’**):

“For crustal earthquakes in regions with attenuative properties **similar** to those of Southern California, the proposed standard equation is

$$ML = \log_{10}(A) + 1.11 \log_{10} R + 0.00189 \cdot R - 2.09, \quad (2)$$

where  $A$  = maximum **trace** amplitude in **nm** that is measured on output from a **horizontal-component** instrument that is filtered so that the response of the seismograph/filter system replicates that of a **Wood-Anderson standard seismograph** but with a static magnification of 1;

$R$  = **hypocentral distance in km**, typically less than 1000 km.

Equation (2) is an expansion of that of Hutton and Boore (1987) (see first equation in Table 2 below). The constant term in equation (2), -2.09, is based on an experimentally determined static magnification of the Wood-Anderson of 2080, rather than the theoretical magnification of 2800 that was specified by the seismograph's manufacturer. The formulation of equation (2) reflects the intent of the *Magnitude WG* that reported *ML* amplitude data not be affected by uncertainty in the static magnification of the Wood-Anderson seismograph.

For seismographic stations containing two horizontal components, amplitudes are measured independently from each horizontal component, and each amplitude is treated as a single datum. There is no effort to measure the two observations at the same time, and there is no attempt to compute a vector average.

For crustal earthquakes in regions with attenuative properties that are **different** than those of coastal California, and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:

$$ML = \log_{10}(A) + C(R) + D, \quad (3)$$

where  $A$  and  $R$  are as defined in equation (2), except that  $A$  may be measured from a **vertical-component** instrument, and where  $C(R)$  and  $D$  have been **calibrated** to adjust for the different regional attenuation and to adjust for any systematic differences between amplitudes measured on horizontal seismographs and those measured on vertical seismographs."

Table 2 gives examples of regional *Ml* calibration functions from different countries and continents followed by explanatory comments. Many more *Ml* calibration functions, but also of other magnitude formulas used by different agencies in Europe, Tunisia, Israel, Iran, Mongolia and French Polynesia have been published in the EMSC-CSEM Newsletter of Nov. 15, 1999 (see <http://www.emsc-csem.org/Documents/?d=newsl>). It can also be downloaded via the list *Download Programs & Files* (see Overview on the NMSOP-2 front page).

**Table 2** Regional calibration functions  $-\log A_0$  for *Ml* determinations.  $\Delta$  - epicentral distance and  $R$  - hypocentral ("slant") distance with  $R = \sqrt{(\Delta^2 + h^2)}$ , both in km ;  $h$  – hypocentral depth in km,  $T$  - period in s, Com. - recording component,  $S$  – station correction.

**Comment 1.1:** Pre-1990 regional calibration relationships in Table 2 were derived by assuming a static magnification of 2800 for the Wood-Anderson seismometer, whereas most of the more recent calibration formulas assumed the empirically derived average value of 2080 according to Uhrhammer and Collins (1990), as does the newly proposed IASPEI standard formula (2). For the response function and poles and zeros of this revised Wood-Anderson standard response see Figure 1 and Table 1 in IS 3.3. Accordingly, one might expect that reducing the constants in the older  $M_L$  formulas by  $0.129 = \log(2800/2080)$  would yield magnitude values that are compatible with the IASPEI (2011) standard formula and most of the post-1990  $M_L$  formulas. However, the re-calibration by Uhrhammer and Collins yielded also another damping factor, namely 0.7 instead of 0.8. (see Table 1 in IS 3.3). With this, the difference between the old and new  $M_L$  relationships becomes slightly frequency-dependent, as mentioned already by Kim (1998). According to D. Bindi (personal communication 2011) this difference is minimum at the response corner frequency of 1.28 Hz, 0.07 m.u. at 1 Hz, 0.08 m.u. at 0.8 Hz and 2 Hz, 0.11 m.u. at 0.5 and 3 Hz and 0.13 m.u. at  $< 0.12$  Hz and  $> 8$  Hz.

**Formulas in Table 2** that have been derived assuming the old WA response are commented in the Reference column by **oWA**, those, which accounted only for the *constant difference* in static response by **cdWA**, but those derived by using the new WA response by **nWA**. While the difference plays no role as long as the amplitudes are measured on records of the original WA seismographs it has to be taken into account, also in its frequency dependence, when producing synthetic WA seismograms. It is, therefore, also not fully correct to follow the approaches by Kanamori et al. (1993) and Pechmann et al. (2007). They used the nominal WA gain of 2800 to construct the synthetic WA seismograms and then accounted for the (assumed constant) gain difference between the synthetic and actual WA records via the station corrections. Station corrections should not only serve a formal purpose, namely to reduce the data scatter and thus improve the precision of magnitude estimates but also have a geophysical meaning which relates to the recording site itself and not to an instrumental bias.

If the procedure used by the authors of formulas presented in Table 2 is not obvious to us, we put a question mark (?) in front. Then consultation of the original publication and/or of the author is recommended.

**Comment 1.2:** Calibration of alternative regional magnitude scales to the standard formula should be made in such a way, that at some specific distance  $\leq 100$  km identical amplitude values inserted in both the standard formula and the alternative regional  $M_L$  formula yield the same magnitude value. Fig. 3.12 in Chapter 3 shows such a mutual scaling of different scales around 50 km epicentral distance. However, for larger distances, due to differences in regional attenuation, the magnitudes resulting from identical amplitude values but using different regional calibration formulas may differ by about one magnitude unit at distances larger than 800 km when comparing, e.g., the standard formula eq. (2) for Southern California (young tectonic region with high heat flow) with the formula by Saunders et al. (2011) for South Africa (stable old continental platform area, low heat flow).

To allow a more meaningful comparison of earthquakes in regions having very different attenuation of waves already within the first 100 km, Hutton and Boore (1987) recommend even a scaling at 17 km hypocentral distance. There, in agreement with the original definition of magnitude in southern California  $M_L = 3$  should correspond to 10 mm of motion on a Wood-Anderson instrument, rather than 1 mm of motion at 100 km (as for Table 1). This scaling recommendation was taken for the near range NW Turkey formula by Baumbach et al. (2003) and by Langston et al. (1998) in Tansania (see Table 2). Yet, the majority of formulas in Table 2 have been scaled to the yield  $M_L = 3$  for measured 1 mm trace motion on a WA record at  $R = 100$  km.

**Comment 1.3:** Station corrections  $S$  for  $M_L$ , based on short-period amplitude measurements, are rather large. They typically range between about  $\pm 0.5$  m.u., are usually larger for horizontal than for vertical component recordings, negative for stations on sediments or weathered rocks and near zero or positive for station sites on hard rock (e.g., Baumbach et al., 2003; Hutton and Boore, 1987; Saunders et al. (2011); Strauch and Wylegalla, 1989; Vidal and Munguía, 1999).

**Comment 1.4:** The first part of the Uhrhammer et al. (2011) calibration function for all California is identical with the expanded Hutton and Boore (1987) relationship for Southern California. However, after several inversions, these authors found out that the best least-square fit to all California data was achieved by a linear combination of the Southern California relationship with a sixth order Chebychev polynomial  $TP(n) \times T(n,z)$ , where  $n$  is summed from 1 to 6 with different coefficients  $TP(1)$  to  $TP(6)$ ,  $T(n, z) = \cos[n \times \arccos(z)]$  and  $z$  being the scale transformation of the epicentral distances  $R$ . For the given data the relationship  $z(R) = 1.11366 \log(R) - 2.00574$  transforms  $R$  in the range  $8 \text{ km} \leq R \leq 500 \text{ km}$  to  $-1 \leq z \leq +1$ . The new  $-\log A_0(R)$  relationship by Uhrhammer et al. (2011) was found to be robust with respect to constraints on the derived stations corrections and ultimately reduced to variance of the data by 50%. It should also be noted that the authors apply a pre-filter to reduce long-period noise.

## 2 Classical and new standard surface wave magnitudes $M_s$ , $M_{s\_20}$ and $M_{s\_BB}$

Gutenberg (1945a) published the following relationship for calculating the surface-wave magnitude  $M_s$  based on measurements of the “absolute” maximum horizontal-component displacement amplitude in units of  $\mu\text{m}$  at periods “around 20 s”:

$$M_s = \log A_{Hmax} + 1.656 \log \Delta + 1.818. \quad (4)$$

Equation (4) is applicable at epicentral distances  $\Delta$  between about  $20^\circ$  and  $130^\circ$ . Richter (1958) published tabulated Gutenberg  $M_s$  calibration values  $\sigma_s(\Delta)$ . They allow to use the Gutenberg surface-wave magnitude formula in its general form  $M_s = \log A_{Hmax}(\Delta) + \sigma_s(\Delta)$  up to  $180^\circ$  (see Table 3).

**Table 3** . Tabulated  $M_s$  calibration values  $\sigma_s(\Delta)$  according to Richter (1958) when  $A_{Hmax}$  is measured in  $\mu m$ .

| $\Delta$ (degrees) | $\sigma_s(\Delta)$ | $\Delta$ (degrees) | $\sigma_s(\Delta)$ | $\Delta$ (degrees) | $\sigma_s(\Delta)$ |
|--------------------|--------------------|--------------------|--------------------|--------------------|--------------------|
| 20                 | 4.0                | 60                 | 4.8                | 120                | 5.3                |
| 25                 | 4.1                | 70                 | 4.9                | 140                | 5.3                |
| 30                 | 4.3                | 80                 | 5.0                | 160                | 5.35               |
| 40                 | 4.5                | 90                 | 5.05               | 170                | 5.3                |
| 45                 | 4.6                | 100                | 5.1                | 180                | 5.0                |
| 50                 | 4.6                | 110                | 5.2                |                    |                    |

**Comments 2.1:** When rounded to the nearest tenth magnitude unit the values in Table 3 agree up to  $130^\circ$  with those calculated by formula (4). However, for larger distances, formula (4) yields magnitudes that are larger than those of Table 3 by 0.05 to 0.55 m.u. Reason: this simple average least-square data fitting relationship accounts only for the decay of amplitudes with distance but not for the energy focusing towards the antipodes, which is more correctly reflected by the average empirical calibration values.

**Comment 2.2:** Gutenberg calculated  $A_{Hmax}$  from the “vectorially” combined maximum amplitudes measured in the N-S and E-W component. These maxima may occur at different times and relate to different (Love and Rayleigh) surface waves. This differs from a true horizontal component vector amplitude maximum, which requires both components to be measured at the same time (within about a quarter of a period). Therefore, classical Gutenberg  $M_s$  values tends to be on average somewhat larger than  $M_s$  based on true vector sum  $A_{Hmax}$  (Figure 1 and comments by Gellert and Kanamori, 1977; Abe and Kanamori, 1980; Lienkaemper, 1984).

**Figure 1** The difference between  $M_s$  derived from these records according to the Gutenberg “vectorial” combination  $A_{Hmax} = (LR_E^2 + LQ_N^2)^{1/2}$  and the true  $A_{Hmax}$  of LR is +0.12 m.u. This is about the largest difference possible (0.15 m.u.) and depends on the BAZ (here  $85^\circ$ ).

**Comment 2.3:** Gutenberg himself did not write in his notebooks, at which period he had measured amplitude A, because he had defined his  $M_s$  scale for “periods of about 20 s”. Yet, comparison with the original bulletins also of other stations used by Gutenberg as data sources for calculating the Gutenberg-Richter  $M_{GR}$  magnitudes in “Seismicity of the Earth” (Gutenberg and Richter, 1954) showed that periods as low as 12 s and as high as 23 s were sometimes used, with values outside of the period range 18 s to 22 s not being rare (Abe, 1981; Lienkaemper, 1984).

Another surface-wave calibration function has been published by Vaněk et al. (1962) and Karnik et al. (1962). It has to be used for true (within half a period in the N-S and E-W component) vectorially combined readings of  $(A_H/T)_{\max}$  in the distance range  $1^\circ < \Delta < 160^\circ$  at periods between  $2 \text{ s} < T < 30 \text{ s}$ . This **formula, which yields in fact a broadband surface-wave magnitude estimate**, has been adopted by IASPEI in 1967 as standard formula for  $M_s$  determination. It reads:

$$M_s = \log (A_H/T)_{\max} + 1.66 \log \Delta + 3.3. \quad (5)$$

Tabulated average calibration values, to which formula (5) had been fitted, were published by Kondorskaya et al. (1981) for the distance range  $1^\circ$  to  $180^\circ$  (see Table 4).

**Table 4**  $M_s$  magnitude calibration values  $\sigma_s(\Delta)$  (according to Kondorskaya et al., 1981) for true vectorially combined horizontal component surface-wave displacement amplitudes (in  $\mu\text{m}$ ) from shallow earthquakes ( $h \leq 60 \text{ km}$ ), which relate to the largest ratio  $(A_H/T)_{\max}$  in the surface-wave group in a wide range of periods between  $2 \text{ s} < T < 30 \text{ s}$ .

| $\Delta^\circ$ | $0^\circ$ | $1^\circ$ | $2^\circ$ | $3^\circ$ | $4^\circ$ | $5^\circ$ | $6^\circ$ | $7^\circ$ | $8^\circ$ | $9^\circ$ |

| $110^\circ$    | 6.69      | 6.70      | 6.70      | 6.71      | 6.72      | 6.72      | 6.73      | 6.74      | 6.74      | 6.75      |
| $120^\circ$    | 6.75      | 6.76      | 6.76      | 6.76      | 6.77      | 6.77      | 6.78      | 6.78      | 6.78      | 6.79      |
| $130^\circ$    | 6.79      | 6.79      | 6.80      | 6.80      | 6.80      | 6.81      | 6.81      | 6.81      | 6.81      | 6.81      |
| $140^\circ$    | 6.82      | 6.82      | 6.82      | 6.82      | 6.83      | 6.83      | 6.83      | 6.83      | 6.83      | 6.83      |
| $150^\circ$    | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      | 6.84      |
| $160^\circ$    | 6.84      | 6.84      | 6.83      | 6.83      | 6.83      | 6.82      | 6.82      | 6.82      | 6.82      | 6.82      |
| $170^\circ$    | 6.81      | 6.81      | 6.80      | 6.79      | 6.77      | 6.74      | 6.71      | 6.69      | 6.64      | 6.59      |
| $180^\circ$    | 6.49      |           |           |           |           |           |           |           |           |           |

**Comment 2.3:** The calibration values in Table 4 agree at epicentral distances between  $1^\circ$  and  $140^\circ$  within 0.05 magnitude units with the values calculated from the calibration term in the Prague-Moscow surface-wave magnitude formula (5). For larger distances, however, this formula overestimates the magnitude between 0.05 and 0.55 (at  $180^\circ$ ) m.u., for the same

reason as the Gutenberg (1945a) formula (4). Therefore, preference should be given to the use of the tabulated values, at least for distances  $>140^\circ$ .

**Comment 2.4:** The calibration values in Table 4 have - since the 1960s - been used at the basic seismic stations of the former Soviet Union (USSR) and its follow-up Commonwealth of Independent States (CIS) countries for  $M_s$  determination from **both horizontal and vertical component readings**. The latter usually relate to the Airy phase of Rayleigh waves ( $R_{\max}$ , see section 2.3 in Chapter 2). Table 5 gives the time difference between  $R_{\max}$  and the P wave as a function of distance. The good agreement between vertical and horizontal component  $M_s$  determinations has also been confirmed by Hunter (1972). Therefore, from May 1975 onwards, also the USGS decided to calculate their  $M_s$  exclusively from vertical component reading using formula (5)..

**Table 5** Approximate time interval ( $t_{R_{\max}} - t_P$ ) between the arrival of the maximum Rayleigh wave amplitude and the first onset of P waves as a function of  $\Delta$  according to Archangelskaya (1959) and Gorbunova and Kondorskaya (1977) (copied from Willmore, 1979).

| 40             | 18-19                         | 85             | 39-40                         | 130            | 60                            |
| 45             | 21                            | 90             | 42                            | 140            | 64                            |
| 50             | 24                            | 95             | 43                            | 150            | 70                            |

Table 6 summarizes the distance-dependent prevailing period ranges at which  $M_s$  according to formula (5) should be calculated. Note that already in Willmore (1979) it is recommended that: **“When the period differs significantly from the values in Table 3.2.2.1 (here Table 6), it may be advisable not to use the data for magnitude determination.”** This, however, is permanently done when measuring the narrowband spectral surface-wave  $M_{s20}$  (see formula (7)).

**Table 6** Distance-dependent prevailing period ranges at which broadband  $M_s$  should be measured (according to Vaněk et al. (1962), Karnik et al. (1962) and Willmore (1979). With currently available very broadband velocity seismographs  $V_{\max}$  may occasionally be observed at even longer period periods up to about 60 s.

| $\Delta^\circ$ | T in s | $\Delta^\circ$ | T in s | $\Delta^\circ$ | T in s | $\Delta^\circ$ | T in s |
|----------------|--------|----------------|--------|----------------|--------|----------------|--------|
| 1              | 3-5    | 10             | 7-10   | 40             | 12-18  | 90             | 16-22  |
| 2              | 4-6    | 15             | 8-15   | 50             | 12-20  | 100            | 16-25  |
| 4              | 5-7    | 20             | 9-14   | 60             | 14-20  | 120            | 16-25  |
| 6              | 5-8    | 25             | 9-16   | 70             | 14-22  | 140            | 18-25  |
| 8              | 6-9    | 30             | 10-16  | 80             | 16-22  | 160            | 18-25  |

**Comment 2.5:** The periods at which  $R_{\max}$  occurs depend on epicentral distance, crust and upper mantle structure along the travel path and the earthquake magnitude. Accordingly, the period of  $R_{\max}$  may vary in a wide range of periods between some 2 and <60 s (see Figures 7 and 8 in Bormann et al., 2009 and related figures in Chapter 3 of this Manual). This notwithstanding, measuring the ratio  $(A/T)_{\max}$  yields rather stable  $M_s$  determinations (Soloviev, 1955). This has been confirmed recently by Bormann et al. (2009) down to local-regional distances and periods as short as 2 to 5 s for dominantly continental travel paths. For chiefly oceanic paths this still has to be proved (or disproved), as well as the distance-dependent period-ranges at which  $R_{\max}$  is observed. This, however, might be more difficult because of the lack of regional seismic networks in ocean areas. For larger magnitudes and epicentral distances, however, the path-dependent variability of periods is much reduced (see Figures 7 and 8 in Bormann et al. (2009).

**Comment 2.6:** Because of the above, the Prague-Moscow formula (6) is now recommended, with slight modification, by IASPEI (2011) for calculating the new **standard broadband surface-wave magnitude  $M_s_{BB}$**  (see IS 3.3):

$$M_s_{BB} = \log_{10}(V_{\max}/2\pi) + 1.66 \log_{10}\Delta + 0.3, \quad (6)$$

where:  $V_{\max}$  = ground **velocity in nm/s** is associated with the maximum trace-amplitude in the surface-wave train, as recorded on a **vertical-component** seismogram that is **proportional to velocity**;

$T$ , the period of the surface-wave, should satisfy the condition **3 s <  $T$  < 60 s**;

$\Delta$  = **epicentral** distance in degrees, with (6) being applicable in the range  **$2^\circ \leq \Delta \leq 160^\circ$** ;

the focal depth  $h$  being **less than 60 km**;

and the term  $\log_{10}(V_{\max}/2\pi)$  replaces the  $\log_{10}(A/T)_{\max}$  term of the original formula (5).

The same calibration terms as in formula (6) is used for the other IASPEI (2011) **standard surface-wave magnitude  $M_s_{20}$** , which is identical with the NEIC/PDE  $M_s$ :

$$M_s_{20} = \log_{10}(A/T) + 1.66 \log_{10}\Delta + 0.3, \quad (7)$$

where:  $A$  = **vertical-component** ground displacement in **nm** measured from the maximum surface-wave trace-amplitude having a period between **18 s and 22 s** on a simulated World-Wide Standardized Seismograph Network (WWSSN) **long-period seismograph** record, with  $A$  being determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-LP response at period  $T$ , and  $\Delta$  = **epicentral** distance in degrees **in the range  $20^\circ \leq \Delta \leq 160^\circ$** .

**Comment 2.7:** Theoretically, for periods  $T = 20$  s, the IASPEI standard formula (5) for  $M_s$  is expected to yield magnitude values that are 0.18 m.u. larger than those derived from the Gutenberg formula (4). This, however, is not confirmed by empirical testing (see Lienkaemper, 1984) and partially due to the fact that Gutenberg did not measure the true maximum vector amplitude (see *Comment 2.2*).

For more detailed discussion and figures on the relationship between  $M_s_{20}$  and  $M_s_{BB}$  see Chapter 3 and Bormann et al. (2009).

### 3 Classical and new standard body-wave magnitudes $mB$ and $mb$

Gutenberg (1945b and c) developed a magnitude formula for teleseismic body waves P, PP and S. He used it in the wide period range between about 2 s and 20 s (Abe, 1981 and 1984; Abe and Kanamori, 1980). The formula reads:

$$mB = \log (A/T)_{\max} + Q(\Delta, h). \quad (8)$$

Thus,  $mB$  is in fact a **medium-period body-wave broadband magnitude**. Gutenberg and Richter (1956) published for the three types of body waves diagrams of  $Q$  values as a function of  $\Delta$  and source depth  $h$  (Figures 1a-c).

Figure 1a

Figure 1b

Figure 1c

Gutenberg and Richter (1956) published also a **table of  $Q(\Delta)$**  values for P, PP and S waves in vertical ( $V = Z$ ) and horizontal (H; vectorially-combined) components **for shallow earthquakes** (Table 7). All G-R  $Q$  values are valid when  $A$  is given in  $\mu\text{m}$  ( $10^{-6}$  m). If  $A$  is measured in nm ( $10^{-9}$  m), as now common in modern analysis programs for processing data with high dynamic range and resolution, the  $Q$  values have to be reduced by -3.

**Table 7** Values of  $Q(\Delta)$  for P, PP and S waves for shallow shocks ( $h \approx 15$  km) according to Gutenberg and Richter (1956) if the ground amplitude is given in  $\mu\text{m}$ .

Besides these original tabulated Gutenberg-Richter Q values for shallow crustal earthquake there exist also tables with values resulting from scanning Figure 1a for vertical component P-wave readings in discrete intervals of source distance and depth. The respective table, produced by the USGS/NEIC, is reproduced in PD 3.1 of this Manual, together with the source code of the program used for interpolation between these tabulated values.

**Comment 3.1:** Until now, this table has been used by the USGS/NEIC exclusively for scaling **short-period narrowband P-wave amplitude readings** at periods around 1 s ( $T < 3s$ ) and **calculating mb by essentially the same formula (8)**. However, instead of looking for the true  $(A/T)_{\max}$  it has become common to measure the maximum trace amplitude in the used short-period narrow-band record, calculate from it the related ground motion amplitude by dividing the trace amplitude by the record magnification at the related period, and then dividing this calculated “ground motion amplitude” by the related period.

**Comment 3.2:** Note that for periods below 4 s differences in frequency-dependent attenuation, which are not accounted for by formula (8), may become significant. For more detailed discussion and figures on this issue see Chapter 3 of this Manual as well as Bormann et al. (2009).

**Comment 3.3:** At the IASPEI General Assembly in Zürich (1967) the Committee on Magnitudes recommended that stations should report the magnitude for all waves for which calibration functions are available, to publish amplitude and period values separately and to correct body-wave magnitudes that were exclusively determined from short-period records. However, aiming at simplifying routine analysis and saving time, it has become wide-spread practice to measure only vertical-component P-wave amplitudes, and in western countries only on short-period narrowband recordings.

**The Gutenberg and Richter (1956)  $Q(\Delta, h)_{PZ}$  values are still the accepted standard calibration values for both mB and mb.**

The now recommended IASPEI (2011) standard formula for broadband mB\_BB reads:

$$mB\_BB = \log_{10}(V_{\max}/2\pi) + Q(\Delta, h) - 3.0 \quad (9)$$

where (quote): “ $V_{\max}$  = ground **velocity in nm/s** associated with the maximum trace-amplitude in **the entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, but ending **preferably** before PP, as recorded on a vertical-component seismogram that is **proportional to velocity**, where the period of the measured phase, T, should satisfy the condition  $0.2 \text{ s} < T < 30 \text{ s}$ , and where T should be preserved together with  $V_{\max}$  in. bulletin data-bases”. Standard mB\_BB is calculated in the **distance range  $20^\circ \leq \Delta \leq 100^\circ$  and for source depths down to 700 km**. However, equation (9) differs from the Gutenberg and Richter (1956) equation (8) for mB by virtue of the  $\log_{10}(V_{\max}/2\pi)$  term, which replaces the classical  $\log_{10}(A/T)_{\max}$  term.

The now recommended IASPEI (2011) standard formulas for mb determination reads:

$$mb = \log_{10}(A/T) + Q(\Delta, h) - 3.0, \quad (10)$$

where (quote): “A = P-wave ground amplitude in **nm** calculated from the maximum trace-amplitude in the **entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, and ending preferably before PP)”;

T = period in seconds of the maximum P-wave trace amplitude with  $T < 3$  s. The distance and depth range of measurement as well as the  $Q(\Delta, h)$  values used are the same as for mb\_BB.

Both T and the maximum trace amplitude are measured **on simulated vertical component WWSSN-SP records**. A is determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-SP response at period T. For the WWSSN-SP response parameters, the tabulated Q-values, and the algorithm used by the USGS/NEIC for mb determination see IS 3.3, respectively PD 3.1 of this Manual.

There is still **another IASPEI (2011) recommended short-period standard magnitude** which is used in the local and regional distance range and has been scaled to be compatible with teleseismic mb. It is also measured on simulated vertical component WWSSN-SP records **in a narrow period range around 1 s** and termed **mb\_Lg**. Its formula reads:

$$\text{mb\_Lg} = \log_{10}(A) + 0.833\log_{10}[r] + 0.4343\gamma(r - 10) - 0.87, \quad (11)$$

where (**quote**): “A = “sustained ground-motion amplitude” in **nm**, defined as the third largest amplitude in the time window corresponding to group velocities of 3.6 to 3.2 km/s, in the period (T) range 0.7 s to 1.3 s, r = **epicentral distance** in **km** and  $\gamma$  = coefficient of attenuation in  $\text{km}^{-1}$ .”

$\gamma$  is related to the quality factor Q through the equation  $\gamma = \pi/(Q \cdot U \cdot T)$ , where U is group velocity and T is the wave period of the  $L_g$  wave.  $\gamma$  is a strong function of crustal structure and should be determined specifically for the region in which the mb\_Lg is to be used.

Arrival times with respect to the origin of the seismic disturbance are used, along with epicentral distance, to compute group velocity U.”

## 4 Body-wave and surface-wave magnitude scales used by the IDC

Another calibration function  $P(\Delta, h)$  for short-period mb determination at periods around 1 s has been elaborated by Veith and Clawson (1972) (see Figure 2). It is based on large sets of vertical-component P-wave recordings of WWSSN-SP seismographs from large explosions at 19 different sites. The  $P(\Delta, h)$  were specifically derived from short-period data and scaled to the level of the Gutenberg-Richter  $Q(\Delta)_{PZ}$  for surface focus.

The  $P(\Delta, h)$  calibration curves are currently used by the International Data Center (IDC) under the Comprehensive Test-Ban Treaty Organisation (CTBTO). However, the short-period filter applied at the IDC to the original broadband records prior to mb measurement does not simulate the standard WWSSN-SP response, which was used to derive the Veith-Clawson calibration curves. Rather, at the IDC one uses a more high-frequency response that peaks at 3.4 Hz (see Figure 16 in IS 3.3). This contributes partially to the earlier saturation of mb(IDC) as compared to mb(PDE) and mb(IASPEI). The other reason is the very short and fixed IDC measurement time-window for P amplitudes within the first 5.5 s after the P onset (see Chapter 17, p. 26-27) which may cause for great earthquakes with magnitudes above 8 differences between mb(IASPEI) and mb(IDC) of more than 1 m.u (see related discussion in section 4.3 of IS 3.3).

**Figure 2** Calibration functions  $P(\Delta, h)$  for mb determination from narrow-band short-period vertical-component records with peak displacement magnification around 1 Hz (WWSSN-SP characteristic) according to Veith and Clawson (1972). **Note:** The  $P(\Delta, h)$  values have to be used in conjunction with maximum P-wave peak-to-trough ( $2A!$ ) amplitudes in units of nanometers ( $1 \text{ nm} = 10^{-9} \text{ m}$ ) (modified from Veith and Clawson (1972). Magnitude from short-period P-wave data, BSSA, **62**(2), p. 446, © Seismological Society of America).

When comparing Figure 1a and Figure 2 it is obvious that the  $P(\Delta, h)$  curves look much smoother than the  $Q(\Delta, h)_{PZ}$  curves. This agrees with the also much smoother preliminary revision of the G-R  $Q(\Delta)$  curve for mB calibration of shallow focus earthquakes by Saul and Bormann (2007) (see Figure 22 in IS 3.3). However, for deep events the  $P(\Delta, h)$  curves have been scaled according to upper mantle attenuation relationships available some 40 years ago, which have not yet been well constrained and still are largely model-dependent. Granville et al. (2005) confirmed that because of the large differences between the Gutenberg-Richter and the Veith-Clawson calibration functions for very deep earthquakes individual event magnitudes  $mb(PDE)$  and  $mb(IDC)$  may differ by several tenths of m.u. Since, however, the main focus of the CTBTO is on the location, magnitude determination and discrimination of shallow earthquakes and underground nuclear explosions (UNEs) these biases in  $P(\Delta, h)$  for deep earthquakes are not so relevant for the IDC assignment. But earthquake seismologists using IDC data should be aware of it and account for systematic  $mb(IDC)$  biases.

The local magnitude scale used by the IDC also differs from the classical  $M_L$  procedure and has been scaled so as to yield magnitude values that are compatible with the teleseismic  $mb(IDC)$ . For details see Chapter 17, Section 7.4.2.1.

More appropriate for global seismology is the use at the IDC of an  $M_s$  calibration relationship that has been specifically derived for the use of 20 s surface-wave amplitude readings. The IDC uses the difference between its  $m_b$  and  $M_s$  as the main criterion for discriminating between natural earthquakes and strong sub-surface explosions. However, Evernden (1971), von Seggern (1977), Herak and Herak (1993) and Rezapour and Pearce (1998) have shown that using the IASPEI standard formula (5) for  $M_s$  based on 20 s surface-wave readings only results in systematic distance-dependent errors up to about 0.6 m.u. On the one hand this is due to the fact that the simple relationship (5) cannot account for the energy focusing of surface-waves towards the antipodes and on the other hand to the fact that for distances  $<60^\circ$  the average periods of Rayleigh surface-wave maxima tend to be smaller than 18 s, down to about 8 s only around  $10^\circ$  (see Table 6 in this Data Sheet, Figure 11 in IS 3.3 and Bormann et al., 2009). Yet the more elaborate Rezapour and Pearce (1998)  $M_s$  relationship for 20 s surface waves compensates for it. It reads, when amplitudes are measured in nm:

$$M_s = \log_{10}(A/T)_{\max} + 1/3 \log_{10}(\Delta) + 1/2 \log_{10}(\sin \Delta) + 0.0046\Delta + 2.370, \quad (12)$$

where the term 0.0046 is  $\gamma$  times  $\log_{10}(e)$  ( $= 0.4343$ ), and  $\gamma$ , the attenuation coefficient.  $\gamma$  was determined empirically by Rezapour and Pearce (1998) to be 0.0105 using a very large data set. Surely, this relationship would also be more appropriate than formula (7) for calculating standard  $M_{s\_20}$ , however, recommendations about new calibration relationships have been beyond the mandate of the current IASPEI Working Group on Magnitude Measurements. Maybe, this matter will be taken up again after several years of strict standard  $M_{s\_20}$  measurements with reduced procedure-dependent errors.

## 5 An experimental calibration function for PKP waves

An experimental calibration function for magnitude determinations, based on short-period vertical-component readings of various PKP phases in the distance range  $145^\circ$  to  $164^\circ$ , has been developed by Wendt (see Bormann and Wendt, 1999). The calibration curves are presented in Figure 3 and  $m_b$  is calculated with the following formula (with  $A$  in  $\mu m$ ):

$$m_b(\text{PKP}) = \log_{10} (A/T) + Q(\Delta, h)_{\text{PKPab,bc,df}}. \quad (13)$$

Extensive use of this relationship at station CLL proved that  $m_b$  determinations from core phases are possible with a standard deviation of less than  $\pm 0.2$  magnitude units as compared to P-wave  $m_b$  determinations by NEIC and ISC. If more than one PKP phase can be identified and  $A$  and  $T$  been measured then the average value from all individual magnitude determinations provides a more stable estimate. The applicability of these calibration functions should be tested with data from other stations of the world-wide network.

**Figure 3** Calibration functions according to S. Wendt for the determination of mb(PKP) for PKPdf, PKPbc and PKPab (see Bormann and Wendt, 1999).

## 6 Other magnitude scales

Besides the above mentioned magnitude scales there exist many other ones. Yet, most of them are less (or no longer) widely used, often only within local networks (such as coda or duration magnitudes), or based on specific instrumentation (e.g., strong-motion magnitudes), or aimed at assessing the “size” of specific earthquake related phenomena (such as tsunami magnitudes). Others are of much younger origin and still in the experimental stage, or highly

based on theory and requiring much more complicated algorithms and procedures than the above described “classical” magnitudes. But in any event, all such alternative or complementary magnitudes have to be scaled in one or the other way to the pioneering magnitudes described above, first and foremost to  $M_L$ ,  $M_s$ ,  $mB$  or  $mb$ . For more details see Chapter 3 of NMSOP-2 and encyclopedia review papers by Bormann (2011) and Bormann and Saul (2009).

Most important amongst these alternative magnitudes are the (supposedly) non-saturating and more physically based moment-magnitude scale  $M_w$  and the complementary energy magnitude scale  $M_e$ . The former has even become – not fully justified when taking the advantages of  $M_e$  into account – the preferred magnitude scale for “unifying” earthquake catalogs as well as for seismic hazard assessment. Yet, the procedures for determining  $M_w$  and  $M_e$  are not yet standardized and too sophisticated to be routinely applicable by ordinary analysts at seismological stations or smaller analysis centres. However, software is already offered which calculates these magnitudes in near real-time based on the online-retrieval of wave-form data from regional and global virtual seismic networks (see Chapter 8 and IS 8.3). But these are black-box systems with usually no more analysis personnel involved. In Chapter 3 of this Manual the procedures for calculating the seismic moment tensor, and  $M_w$  as part of it, as well as the released seismic wave energy and related  $M_e$ , are described in detail, while Bormann and Di Giacomo (2011) outline in detail the common roots, differences and benefits of complementary use of  $M_w$  and  $M_e$ .

## 1 Aim

The exercises aim at making you familiar with the measurement of seismic amplitudes and periods in analog and digital records and the determination of related **classical magnitude** values for local and teleseismic events by using the related procedures and relationships outlined in Chapter 3, and the relevant classical magnitude calibration functions given in DS 3.1. For international measurement standards, recently adopted by IASPEI (2011) for local, regional and teleseismic magnitudes, see IS 3.3 and [http://www.iaspei.org/commissions/CSOI/Summary\\_WG-Recommendations\\_20110909.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG-Recommendations_20110909.pdf). Guidelines and waveform data for an interactive training to measure these standard amplitude, period and magnitudes parameters by using the analysis program SEISAN are given in IS 3.4. This IS will be updated in future when other analysis programs suitable for measuring the standard data become available.

## 2 Procedures

The general relationship 
$$M = \log (A/T) + \sigma(\Delta, h) \quad (1)$$

is used for magnitude determination, with A – maximum “ground motion” amplitude in  $\mu\text{m}$  ( $10^{-6}$  m) or nm ( $10^{-9}$  m), respectively, measured for the considered wave group, T – period of that maximum amplitude in seconds. Examples, how to measure the related trace amplitudes B and period T in seismic records are depicted in Fig. 3.9. Trace amplitudes B have to be divided by the respective magnification  $\text{Mag}(T)$  of the seismograph at the considered period T in order to get the “ground motion” amplitude in either  $\mu\text{m}$  or nm, i.e.,  $A = B/\text{Mag}(T)$ .

$\sigma(\Delta, h) = -\log A_0$  is the magnitude calibration function where  $\Delta$  = epicentral distance and h = source depth. For teleseismic body waves the calibration function is usually termed  $Q(\Delta, h)$ , according to Gutenberg and Richter (1956), who published respective calibration values for medium-period vertical as well as horizontal component amplitude readings of P and PP waves and for horizontal component S-wave amplitudes. Another calibration function for short-period vertical component P-wave amplitude readings, termed  $P(\Delta, h)$ , has been published by Veith and Clawson (1972). For *teleseismic events* (distance >1000-2000 km)  $\Delta$  is generally given in degree ( $1^\circ = 111.19$  km), for *local/near regional events* (distance usually <1000 km), however, in km. For local events often the “slant range” or hypocentral distance R (in km) is used instead of  $\Delta$ . All calibration functions used in the exercise are given in DS 3.1.

**Note:** According to the original definition of the local magnitude scale  $M_l$  by Richter (1935) only the *maximum trace amplitude* B in mm as recorded in standard records of a Wood-Anderson seismometer is measured (see Fig. 3.11 and section 3.2.4), i.e.,

$$M_l = \log B(\text{WA}) - \log A_0(\Delta). \quad (2)$$

Accordingly, no period  $T$  is measured, and no conversion to “ground motion” amplitude is made. However, when applying  $M_L$  calibration functions to trace amplitudes  $B$  measured (in mm too) in records of another seismograph (SM) with a frequency-magnification curve  $\text{Mag}(T)$  different from that of the Wood-Anderson seismograph (WA) then this frequency-dependent difference in magnification has to be corrected. Equation (2) then becomes

$$(3) \quad M_L = \log B(\text{SM}) + \log \text{Mag}(\text{WA}) - \log \text{Mag}(\text{SM}) - \log A_0.$$

### 3 Data

The data used in the exercise are given in the following figures and tables.

**Figure 1** Vertical component records of a local seismic event in Poland at the stations CLL and MOX in Germany at scale 1:1. The magnification values  $\text{Mag}(\text{SM})$  as a function of period  $T$  for this short-period seismograph are given in Table 1 below.

**Table 1** Magnification values  $\text{Mag}(\text{SM})$  as a function of period  $T$  in s for the short-period seismograph used for the records in Figure 1 together with the respective values  $\text{Mag}(\text{WA})$  for the Wood-Anderson standard seismograph for  $M_L$  determinations.

| $T$ (in s) | $\text{Mag}(\text{SM})$ | $\text{Mag}(\text{WA})$ | $T$ (in s) | $\text{Mag}(\text{SM})$ | $\text{Mag}(\text{WA})$ |
|------------|-------------------------|-------------------------|------------|-------------------------|-------------------------|
| 0.1        | 35,000                  | 2,800                   | 1.1        | 190,000                 | 1,100                   |

**Figure 2** Analog record at scale 1:1 of a Kirnos-type seismograph from a surface-wave group of a teleseismic event. Scale: 1 mm = 4 s; for displacement  $\text{Mag} = V$  see inserted table.

**Figure 3** Display of the long-period (10 to 30 s) filtered section of a broadband 3-component record of the Uttarkasi earthquake in India (19 Oct. 1991;  $h = 10 \text{ km}$ ) at station MOX in Germany. The record traces are, from top to bottom: E, N, Z. Marked are the positions, from where the computer program has determined automatically the ground displacement amplitudes  $A$  and related periods  $T$  for the onsets (from left to right) of P, PP and S. For S the respective cycle is shown as a bold trace. The respective values of  $A$  and  $T$  for all these phases are saved component-wise in the data-pick file. They are reproduced in the box on the right together with the computer picked onset-time difference  $S - P$  and the epicentral distance  $\Delta$  as published for station MOX by the ISC.

**Figure 4** As for Figure 3, however short-period (0.5 to 3 Hz) filtered record section of the P-wave group only. Note that the amplitudes are given here in nm ( $10^{-9}$  m).

## 4 Tasks

### Task 1:

- 1.1 Identify and mark in the records of Figure 1 the onsets Pn, Pg and Sg. Note that Pn amplitudes are for distances  $< 400$  km usually smaller than that of Pg! Then determine the hypocentral (“slant”) distance  $R$  in km from the rule of thumb  $t(\text{Sg-Pg})[\text{s}] \times 8 = R [\text{km}]$  for both station CLL and MOX. Note, that for this shallow event the epicentral distance  $\Delta$  and the hypocentral distance  $R$  are practically the same.
- 1.2 Determine for the stations CLL and MOX the max. trace amplitude  $B(\text{SM})$  and related period  $T$  and then, according to Equation (3), the equivalent log trace amplitude when recorded with a Wood-Anderson seismometer, i.e.,  $\log B(\text{WA}) = \log B(\text{SM}) + \log \text{Mag}(\text{WA}) - \log \text{Mag}(\text{SM})$ .
- 1.3 Use Equation (2) above, and the values determined under task 1.2, for determination of the local magnitude  $M_L$  for the event in Figure 1 for both station CLL and MOX using the calibration functions  $-\log A_0$ :
  - a) by Richter (1958) for California (see Table 1 in DS 3.1);
  - b) by Kim (1998) for Eastern North America (vertical comp.; see Table 2 in DS 3.1);
  - c) by Alsaker et al. (1991) for Norway (vertical comp., see Table 2 in DS 3.1).
- 1.4 Discuss the differences in terms of:
  - a) differences in regional attenuation in the three regions from which  $M_L$  calibrations functions were used;
  - b) amplitude differences within a seismic network;
  - c) uncertainties of period reading in analog records with low time resolution and thus uncertainties in the calculation of the equivalent Wood-Anderson trace amplitude  $B(\text{WA})$ .

### Task 2:

- 2.1 Measure the *maximum* horizontal and vertical trace amplitudes  $B$  in mm and related periods in s from the 3-component surface-wave records in Figure 2. Note, that the maximum horizontal component has to be calculated by combining vectorially  $B_N$  and  $B_E$ , measured at the same record time, i.e.,  $B_H = \sqrt{B_N^2 + B_E^2}$ .
- 2.2 Calculate the respective maximum ground amplitudes  $A_H$  and  $A_V$  (in  $\mu\text{m}$ ; vertical  $V = Z$ ) by taking into account the period-dependent magnification of the seismograph (see table inserted in Figure 2)
- 2.3 Calculate the respective surface-wave magnitudes  $M_s$  according to the calibration function
  - a)  $\sigma(\Delta)$  as published by Richter (1958) (see Table 3 in DS 3.1, for horizontal component  $H$  only);
  - b)  $\sigma(\Delta)$  as given by the Prague-Moscow formula  $M_s = \log(A/T)_{\max} + 1.66 \log \Delta + 3.3$  (Vaněk et al., 1962), which has been accepted by IASPEI in 1967 as the standard

formula for surface-wave magnitude determinations. Apply it to both the horizontal and the vertical component amplitude and period readings.

**Note:** Differentiate between surface-wave magnitudes from horizontal and vertical component records by annotating them unambiguously as MLH and MLV, respectively.

### Task 3:

Use the computer determined periods and amplitudes given in the right boxes of Figures 3 and 4 for the body-wave phases P, PP and S recorded from the shallow ( $h = 10$  km) teleseismic earthquake in India in order to determine the respective body-wave magnitudes according to the general relationship (1):

3.1 Compare the epicentral distance calculated by the ISC for MOX ( $\Delta = 52.76^\circ$ ) with your own quick determination of  $\Delta$  using the “rule of thumb”  $\Delta$  (in  $^\circ$ ) =  $[t_{S-P}(\text{in min}) - 2] \times 10$ .

3.2 Compare the differences in  $Q(\Delta)$  according to Table 7 in DS 3.1 when using the “exact” distance given by the ISC with your quick “rule of thumb” estimation of  $\Delta$ . Assess the influence of the distance error on the magnitude estimate and draw conclusions.

3.3 Calculate MPV, MPH; MPPV, MPPH and MSH using the calibration functions  $Q(\Delta)$  given in Table 7 of DS 3.1, the amplitude-period values given in Figure 3 and  $\Delta = 53^\circ$ . Discuss the degree of agreement/disagreement and possible reasons.

3.4 Calculate  $m_b$  for the short-period P-wave recording in Figure 4 using

- $Q(\Delta, h)$  as depicted in Figure 1a of DS 3.1 for the vertical component of P and
- $P(\Delta, h)$  as depicted in Figure 2 of DS 3.1.
- Discuss the difference between a) and b).

## 5 Solutions

**Note:** Your individual readings of times, periods and amplitudes should not deviate more than 10 % and your magnitude estimates should be within about  $\pm 0.2$  units of the values given below.

### Task 1:

- 1.1 CLL  $t(\text{Sg-Pg}) = 26 \text{ s}$   $R = 208 \text{ km}$   
 MOX  $t(\text{Sg-Pg}) = 40 \text{ s}$   $R = 320 \text{ km}$
- 1.2 CLL:  $B(\text{MS}) = 10 \text{ mm}$   $T = (0.5\text{s}?)$   $\log B(\text{WA}) = -0.888$   
 MOX:  $B(\text{MS}) = 18 \text{ mm}$   $T = 1 \text{ s}$   $\log B(\text{WA}) = -0.967$
- 1.3 CLL:  $M_l(\text{Richter}) = 2.7$   $M_l(\text{Kim}) = 2.6$   $M_l(\text{Alsaker}) = 2.4$   
 MOX:  $M_l(\text{Richter}) = 3.1$   $M_l(\text{Kim}) = 2.8$   $M_l(\text{Alsaker}) = 2.6$

1.5 California is a tectonically younger region and with higher heat flow than Eastern North America and Scandinavia. Accordingly, seismic waves are more strongly attenuated with distance. This has to be compensated by larger magnitude calibration values –  $\log A_0$  for California. But even within a seismic network amplitude variations may be, depending on different conditions in local underground and azimuth dependent wave propagation, in the order of a factor 2 to 3 in amplitude, thus accounting for magnitude differences in the order of up to about  $\pm 0.5$  magnitude units between the various stations. This scatter can be reduced by determining station corrections for different source regions. Note also, that the period reading is rather uncertain for CLL. If we assume, as for MOX, also  $T = 1 \text{ s}$  then  $\log B(\text{WA}) = -1.222$ , i.e., the magnitudes values for CLL would be even smaller by 0.3 units.

### Task 2:

- 2.1  $B_N = 20.5 \text{ mm}$ ,  $T_N = 22 \text{ s}$ ;  $B_E = 12 \text{ mm}$ ,  $T_N = 20 \text{ s}$   $\rightarrow B_H = 23.8 \text{ mm}$ ,  $\bar{T} = 21 \text{ s}$   
 $B_Z = 23 \text{ mm}$ ,  $T_Z = 18 \text{ s}$
- 2.2  $A_H = 31.3 \mu\text{m}$  for  $T = 21 \text{ s}$   $A_Z = A_V = 24.2 \mu\text{m}$  for  $T = 18 \text{ s}$
- 2.3 a)  $M_s = \text{MLH}(\text{Richter}) = \log A_{H\text{max}} + \sigma(\Delta)_{\text{Richter}} = 1.5 + 5.15 = 6.65$   
 b)  $M_s = \log(A/T)_{\text{max}} + 1.66 \log \Delta + 3.3 \rightarrow M_s = \text{MLH} = 6.82$  and  
 $M_s = \text{MLV} = 6.78$

**Discussion:** For the given record example  $M_s(\text{Richter}, 1958)$  yields somewhat smaller values than  $M_s(\text{Vaněk et al., 1962})$ . The latter formula, although derived for horizontal component surface-wave amplitude readings, yields comparable magnitude values also when applied to vertical component readings (here difference  $< 0.05$  magnitude units).

### Task 3:

- 3.1 The “rule of thumb” yields  $\Delta = 54.5^\circ$ . This is only  $1.7^\circ$  off the ISC determination. Generally, the rule-of-thumbs allows to estimate  $\Delta$  in the range  $25^\circ < \Delta < 100^\circ$  with an error not larger than  $\pm 2.5^\circ$ .
- 3.2 The deviations in  $Q(\Delta)$  and thus between magnitude estimates based on either  $\Delta$  values from NEIC/ISC calculations or quick S-P determinations at the individual stations and using the “rule of thumb” are generally less than 0.2 units. They are even smaller, when correct travel-time (difference) curves are available. This permits sufficiently accurate quick teleseismic magnitude estimates at individual stations even with very modest tools

and without prior knowledge of the event locations and distance determinations of the world data centers.

3.3 MPV = 6.45, MPH = 6.36, MPPV = 6.36, MPPH = 6.24; MSH = 6.75

The magnitude values for vertical and horizontal component amplitude readings of P and PP, respectively, agree within 0.1 magnitude units. This speaks of a good scaling of the respective  $Q(\Delta)$  calibration functions. MSH is in the given case significantly larger. This is obviously related to the different azimuthal radiation pattern for P and S waves and was one of the reasons, why Gutenberg strongly recommended the determination of the body-wave magnitudes for all these phases and averaging them to a unified body-wave magnitude value  $m$ . The latter provides more stable and less azimuth-dependent individual magnitude estimates.

3.4 a)  $Q_{PZ}(53^\circ, 10 \text{ km}) = 7.0$ ,  $\log(A/T) = -0.19$  (with  $A$  in  $\mu\text{m}$ !)  $\rightarrow$  MPV = mb = 6.8

b)  $P_Z(53^\circ; 10 \text{ km}) = 3.4$ ,  $\log(A/T) = 3.1$  (**with 2A in nm!**)  $\rightarrow$  MPV = mb = 6.5

c)  $P_Z(\Delta, h)$  yields, for the same ratio  $\log(A/T)$ , slightly lower magnitude values as compared to  $Q_{PZ}(\Delta, h)$ , for deep events, in particular. This also applies for other distance ranges (see Figures 1a and 2 in DS 3.1). Note that  $P_Z$ , although specifically developed for the calibration of short-period P-wave amplitudes, is not yet a recommended standard calibration functions.

## 1 Aim

Fault-plane solutions are nowadays routinely calculated and plotted by a diversity of software programs. They may result from using different types of seismic waves, recorded in different frequency bands and ranges of epicentral distances and by measuring and analyzing different record parameters. Accordingly, such solutions, may be based on more sophisticated optimal waveform fitting between real and synthesized records, on considering azimuthal variations in amplitude ratios between P and S waves, or on simple “classical” P-wave first-motion polarity readings only. The latter is still the most common procedure for masses of data, especially when recorded in the local distance and low magnitude range.

However, the under-laying assumptions, sequential procedural steps and ranges of possible errors of fault-plane solutions are often not sufficiently well known to the common user of such data and programs. Therefore, it is recommendable that at least once the step-by-step determination of a fault-plane solution by hand, based on first-motion polarity readings, should be part of the educational program of any future seismologist or geoscientist, as an eye-opening and awareness creating exercise. For this we have selected a realistic yet not too simple and data-wise not too ideally constrained example based on recordings of local aftershocks.

The exercise aims at:

- understanding how fault slip affects the polarities of P waves;
- understanding, how the applied crustal model in the source location process may influence the calculated take-off angles as a function of epicentral distance;
- understanding the presentation of P-wave polarities in an equal angle Wulff net or an equal area projection (Lambert-Schmidt net) of the focal sphere;
- constructing a fault-plane solution and determining the related parameters (**P** and **T** axes and displacement vector) for a real earthquake;
- relating the directions of the fault-plane solutions to the tectonic setting and complementary information on the regional stress pattern.

## 2 Data and procedures

Before a fault-plane solution for a teleseismic event can be constructed, the following steps must be completed:

- a) Interpretation of P-wave first-motion polarities from seismograms at several stations;

- b) Calculation of epicentral distances and source-to-station azimuths for these stations;
- c) Calculation of the take-off angles  $\Theta$  for the seismic P-wave rays leaving the hypocenter towards these stations.

Both b) and c) require the knowledge of the focal depth and of the P-wave velocity-depth function along the ray path (see EX 3.3). Commonly, standard Earth velocity models are used (e.g., Kennett, 1991 or AK135, Kennett et al., 1995; see DS 2.1), especially, when teleseismic recordings are analyzed. Most location programs provide both the source-station azimuths and take-off angles in their output files. In the case of local events, however, it is necessary to determine beforehand, which P-wave travel-time branch is arriving first at what distance. This is strongly influenced by the velocity model of the local crust. Therefore, the events should be located, if possible, with a layered velocity model that represents reasonably well the Earth crust of that region. If it deviates significantly from the global model, significantly biased take-off angles from the source may be calculated for the first arriving P-wave rays. This may result in not separable polarity patterns and thus inconsistent or biased fault-plane solutions.

The exercise below is based on related general definitions, relationships and diagrams presented in Chapter 3 of this Manual in the section “Determination of fault-plane solutions.” The starting data for the exercise are summarized in Table 1. They relate to a locally recorded aftershock of the  $M_s = 6.8$  Erzincan earthquake in Turkey (**Main shock**: 13.03.1992, 39.72°N, 39.63°E; **aftershock**: 12.04.1992,  $M_l = 2.8$ , 39.519° N, 39.874° E, source depth  $h = 3$  km). The distances of the recording stations range from 3.7 km to 49.6 km. They were calculated according to steps a)-c) by using the program HYPO71 (Lee and Lahr, 1975).

**Note:** In the special case of a near surface source in a homogeneous or a plane layered velocity model the take-off angles  $\Theta$  from the source agree with the *angle of incidence*  $A_{IN}$  calculated with HYPO71 for the respective seismic ray arriving at a given station. Figure 1 defines  $\Theta$ , which depends on source distance, source depth, velocity model and the recorded first arriving type of P wave. Further, for an average single layer crustal model of 30 to 40 km thickness, all P-wave first arrivals within a distance of about 120 km to < 200 km are  $P_g$  and up-going. That is, they emerge only from the upper half of the focal hemisphere. Also, when using HYPO71 with the average global two-layer crust according to the velocity model IASP91 (Kenneth 1991) only upper hemisphere take-off angles would have been calculated for the first P-wave arrivals up to distances of 50 km. But in the epicentral area under consideration a significant velocity increase in the upper crust was already found at 4 km depth (increase of  $v_p = 5.3$  km/s to 6.0 km/s). Therefore, a single-layer model above half-space for the upper crust had to be used in the calculations. Accordingly, only stations up to 17 km distance were reached by first arriving rays that left through the upper focal sphere. At larger distances the first arriving P waves had left the lower focal sphere. They were refracted back at this upper crustal discontinuity under the critical angle of incidence  $i_{cr}$ , which is in our layer model 62° according to the velocity contrast  $v_1/v_2 = 5.3/6.0 = \sin i_{cr} = \sin \Theta_{cr}$ . These critically refracted P-waves travel with a constant apparent horizontal velocity of 6.0 km/s and therefore arrive at stations beyond 17 km epicentral distance also with a constant incidence angle  $A_{IN_{cr}} = 62^\circ$  (Figure 2).

Fault-plane solutions are derived by remapping the penetration points of seismic rays through the upper and lower hemisphere on a suitable horizontal plane net projection and separating from each other sectors of opposite polarity by pairs of orthogonal great circles. However, as

obvious from Figures 1 and 2, the polarities of rays leaving the upper and lower hemisphere with the same azimuth are mirrored. Mapping them both with their originally calculated values  $\Theta$  and azimuth AZM on the same horizontal net projection would result in incompatible polarity plots. Therefore, one has to make up one's mind, whether one uses only upper or lower hemisphere polarities and has then to mirror the other hemisphere data so that they become compatible with the reference hemisphere data.

For the exercise we use only lower hemisphere data, as generally used when analyzing teleseismic polarity readings. Thus, for all upper hemisphere polarities with  $90^\circ < \Theta \leq 180^\circ$  corrected values  $\Theta_c$  and  $AZM_c$  have to be calculated by using the relationships given in Figure 1. Only these corrected upper hemisphere polarities can be plotted jointly with the original lower hemisphere polarities ( $0^\circ \leq \Theta \leq 90^\circ$ ) on the same net projection.

**Table 1** Original and corrected (not yet calculated) values of ray azimuth (AZM and  $AZM_c$ ) and take-off angles ( $\Theta$  and  $\Theta_c$ , respectively) towards stations of a temporary network at epicentral distance DIS which recorded the Erzincan aftershock of April 12, 1994. POL - polarity of P-wave first motions. D = **down** = negative (-) first half-wave and U = **up** = positive (+) first half-wave in vertical component records.

| STA | DIST<br>(km) | AZM<br>(degree) | $\Theta$<br>(degree) | POL | $AZM_c$<br>(degree) | $\Theta_c$<br>(degree) |
|-----|--------------|-----------------|----------------------|-----|---------------------|------------------------|
| ALI | 3.7          | 40              | 130                  | D   |                     |                        |

| AKS | 48.7         | 284             | 62                   | D   |                     |                        |
| SUT | 49.6         | 295             | 62                   | U   |                     |                        |

**Figure 1** Transformation of a ray leaving the focal sphere upwards with a take-off angle  $\Theta$  between  $90^\circ < \Theta \leq 180^\circ$  into an equivalent downward ray with same polarity but corrected take-off angle  $\Theta_c$  and azimuth  $AZM_c$ .

**Figure 2** Two rays, leaving the focal sphere in opposite directions, reach - because of the symmetry of radiation pattern - the stations 1 and 2 with the same polarity. The crossing point of the up-going ray with the focal sphere can, therefore, be remapped according to the formulas given in Figure 1 into a crossing point with the lower hemisphere which coincides with the ray crossing-point for station 2.

**Note:**  $\Theta$  calculations based on strongly biased velocity models might result in inconsistent fault-plane solutions or not permit a proper separation of opposite polarity readings into quadrants (as in Figure 4) at all.

The primary data in Table 1 were taken from the output file of the program HYPO71 with which the event was located. The first five columns of this file contain, as an example for the two stations ALI and ESK in Table 1, the following data:

| STN | DIST | AZM | AIN | PRMK |
|-----|------|-----|-----|------|
| ALI | 3.7  | 40  | 130 | IPD0 |
| ESK | 22.7 | 312 | 62  | IPU1 |

with STN - station code; DIST - epicentral distance in km; AZM - azimuth towards the station clockwise in degree from north; AIN (**replaced by us by  $\Theta$** ) - take-off angle of the ray leaving the source towards the station, measured as in Figure 1, and calculated for the given structure-velocity model; PRMK - P-wave reading remarks. In the column PRMK P stands for P-wave onset, I for impulsive (sharp) or E for emergent (less clear) onset, D for clear (or – for poor) downward first motion, U for clear (or + for poor) upward first motion as read at the station. The last character may range between 0 and 4 and is a measure of the quality (clarity) of the onset and thus of the weight given to the reading in the calculation procedure, e.g., 4 for zero weight and 0 for full weight. In case of the above two stations the values for ALI would need to be corrected to get the respective values for the equivalent lower hemisphere ray, i.e.,  $\Theta_c = 180^\circ - 130^\circ = 50^\circ$  and  $AZMc = 180^\circ + 40^\circ = 220^\circ$  while the values for ESK can be taken unchanged from the HYPO71 output file.

The P-wave polarities are commonly plotted according to the take-off angles and azimuths of their rays on either the Wulff or the Lambert-Schmidt net (Figures 3a and b; Aki and Richards, 1980, Vol. 1, p. 109-110). The latter yields less cluttered data plots when  $\Theta < 45^\circ$ , but in principle the fault planes are constructed in the same manner (see EX 3.3).

**Figure 3** a) the equal-angle Wulff net and b) the equal-area Lambert-Schmidt net.

The following relationships hold between the radius  $r$  (in cm) of the respective nets and the distance  $d$  (in cm) from the net center at which the take-off angle  $\Theta$  has to be mapped in the direction of the azimuth AZM:

Wulff net:  $d = r \cdot \tan(\Theta/2);$

Lambert-Schmidt net:  $d = r \cdot \sin(\Theta/2).$

**Note:** In both projections only the equator and the meridians **are great circles**. **Also:** All cut traces of the (possible) fault plane(s) through the focal sphere, which separate the segments of opposite polarity observations, have to be great circles. The amplitude radiation pattern of point source foci is commonly assumed to be spherically symmetric (Figure 4). For deviations see Chapter 3.

**Figure 4** Radiation pattern of the radial displacement component (P wave) due to a double-couple source: a) for a plane of constant azimuth (with lobe amplitudes proportional to  $\sin 2\theta$ ) and b) over a sphere centered on the origin. Plus and minus signs of various sizes denote amplitude variation (with the spherical coordinates  $\theta$  and  $\phi$ ) of outward (+; extensional quadrant) and inward (-; compressional quadrant) directed motions. The fault plane and auxiliary plane are nodal lines on which  $\cos \phi \sin 2\theta = 0$ . The pair of open arrows in a) at the center denotes the shear dislocation and **P** and **T** in b) mark the penetration points of the pressure and tension axes, respectively, through the focal sphere. Note the alternating quadrants of inward (D, -) and outward directed motions (U, +); (modified from Aki and Richards 1980; with kind permission of the authors).

According to the above, basically three steps are required for obtaining a fault-plane solution:

- (1) Calculating the positions of the penetration points of the seismic rays through the focal sphere. They are defined by the azimuth AZM and the take-off angle  $\Theta$  at which the ray leaves the source.
- (2) Marking these penetration points through the upper or lower hemisphere in a horizontal projection of that sphere by using different symbols for upward U (+) and downward D (–) directed first motions of P waves in vertical component records. Usually, lower hemisphere projections are used. Rays which have left the upper hemisphere have to be transformed into their equivalent lower hemisphere rays. This is possible because of spherical symmetry of the radiation pattern (see Figure 4).
- (3) Partitioning the projection of the lower focal sphere by two perpendicular great circles which separate all (or at least most) of the U (+) and D (–) arrivals in different quadrants.

Figure 5 shows the angles which describe the orientation and motion in space of a fault plane. The fault **strike angle**  $\phi_s$  is measured clockwise against North ( $0^\circ \leq \phi_s \leq 360^\circ$ ). To resolve the  $180^\circ$  ambiguity, it is assumed that when standing in the center of the net and looking into the strike direction of the fault it dips to the right hand side (i.e., its fault-trace projection is towards the right of the net center). The **dip angle**  $\delta$  describes the inclination of the hanging wall against the horizontal ( $0^\circ \leq \delta \leq 90^\circ$ ). The **rake angle**  $\lambda$  describes the displacement of the hanging wall relative to the foot wall ( $-180^\circ \leq \lambda \leq 180^\circ$ ).  $\lambda = 0$  corresponds to slip in strike direction,  $\lambda > 0$  means upward motion of the hanging wall (i.e., *reverse or thrust faulting component*) and  $\lambda < 0$  downward motion (i.e., *normal faulting component*). In other words: If the net center is located in the tension quadrant (+) or in the pressure quadrant (–) the fault has a thrust component or a normal component, respectively. The normal or thrust character of the fault-plane solution does not depend on which of the two nodal planes is the active fault plane.

**Figure 5** Angles describing the orientation and motion of faults (see text).

Figure 6 illustrates the measurement of these angles and of additional fault parameters in the net projections. P1, P2 and P3 mark the positions of the poles of the planes FP1 (fault plane), FP2 (auxiliary plane) and EP (equatorial plane) in their net projections. All three planes are perpendicular to each other (i.e.,  $90^\circ$  apart) and intersect in the poles of the respective third plane, i.e., FP1 and FP2 in P3, FP1 and EP in P2 etc.

**Figure 6** Determination of the fault plane parameters  $\phi_s$ ,  $\delta$  and  $\lambda$  in the net diagrams. The polarity distribution, slip direction and projection of FP1 shown here correspond to the faulting case depicted qualitatively in Figure 4. **Note:**  $\lambda^* = 180^\circ - \lambda$  when the center of the net lies in the tension (+) quadrant (i.e., event with thrust component) or  $\lambda^* = -\lambda$  when the center of the net lies in the pressure quadrant (i.e., event with normal faulting component). P1, P2 and P3 are the poles (i.e.,  $90^\circ$  off) of FP1, FP2 and EP, respectively. **P** and **T** are the penetration points (poles) of the pressure and tension axes, respectively, through the focal sphere. + and – signs mark the quadrants with upward and downward P-wave first motions in vertical component records, respectively.

**Note:** On the basis of polarity readings alone it can not be decided whether FP1 or FP2 was the active fault. Discrimination from seismological data alone is still possible but requires additional study of the *directivity effects* such as azimuthal variation of frequency (*Doppler effect*), amplitude ratios and/or waveforms (see Chapter 3). For sufficiently large shocks these effects can more easily be studied in low-frequency teleseismic recordings while in the local distance range, high-frequency waveforms and amplitudes may be strongly influenced by resonance effects due to low-velocity near-surface layers. Seismotectonic considerations or field evidence from surface rupture in case of strong shallow earthquakes as well as aftershock distribution may allow to resolve this ambiguity, too. For “cartoons” of several basic types of earthquake faulting and their related fault-plane solutions in so-called “beach-ball” presentations of the net projections see Chapter 3.

### 3 Tasks

#### Task 1:

If in Table 1  $\Theta > 90^\circ$ , then correct the take-off angles and azimuths in Table 1 for lower hemisphere projection:  $\Theta_c = 180^\circ - \Theta$ ,  $AZMc = AZM(<180^\circ) + 180^\circ$  or  $AZM(\geq 180^\circ) - 180^\circ$ . In case of  $\Theta < 90^\circ$  the original values remain unchanged.

#### Task 2:

Reproduce the Wulff net or the Lambert-Schmidt net projection in Figure 3, best on A4 paper with a radius  $r = 8$  cm. Place a tracing paper or a transparency sheet over the net. Mark on it the center and perimeter of the net as well as the N, E, S and W directions. Pin the marked center of the transparency sheet with a needle to the center of the net copy on paper.

#### Task 3:

Mark the azimuth of the station on the perimeter of the transparency and rotate the latter until the tick mark is aligned along an azimuth of  $0^\circ$ ,  $90^\circ$ ,  $180^\circ$  or  $270^\circ$ . Measure the take-off angle  $\Theta$  from the center of the net along this azimuth. This gives the intersection point of the particular P-wave ray with the lower hemisphere. Mark on this position the P-wave polarity with a **distinct** + for compression or o for dilatation (U or D in Table 1) using *different colors* for better distinction of closely spaced polarities of different sign. **Note:** For calculating the proper distance  $d$  of the polarity entry from the center of the respective net you may also use the respective formulas given above for the Wulff net and the Lambert-Schmidt net as a function of  $r$  and  $\Theta$ . In case that rays left the source through the upper hemisphere ( $\Theta > 90^\circ$ )  $\Theta_c$  and  $AZMc$  for lower hemisphere projection have to be plotted.

#### Task 4:

Rotate the transparent sheet with the plotted data over the net and try to find a **great circle** (**meridian** on the net copy) which separates as good as possible the expected quadrants with different first motion signs. This great circle represents the intersection trace of **one of the possible fault** (or nodal) **planes** (FP1) with the lower half of the focal sphere.

**Note:** Inconsistent polarities that are close to each other may be due to uncertainty in reading correctly the first motion direction of P-wave arrivals with low signal-to-noise ratio or to an incorrect velocity model for calculating the take-off angle. Yet, small P-wave amplitudes are to be expected for take-off angles near to the nodal (fault) planes. Thus, clusters of inconsistent polarities may guide your “eye fit” in finding the best separating great circle. Also computer programs for finding best fitting fault-plane solutions try to minimize both the number of misfitting polarities in the quadrants as well as their distance from the nodal plane. However, be aware that isolated inconsistent polarities may also be due to false polarity switching of the seismometer output or simply by reading errors on the seismic record.

#### Task 5:

Mark point A at the middle of the FP1 projection and find, perpendicular to FP1 and  $90^\circ$  apart, the pole P1 of FP1 (see Figure 6). All great circles, passing this pole are perpendicular to the FP1. Since the second possible fault (auxiliary) plane (FP2) must be perpendicular to the FP1, it has to pass P1. Find, accordingly, a great circle FP2 which again has to separate areas of different polarity.

**Task 6:**

Find the pole P2 for FP2 (which lies on FP1) and delineate the equatorial plane EP. The latter is perpendicular to both FP1 and FP2, i.e., it is a great circle through the poles P1 and P2. The intersection point of FP1 and FP2, P3, is the pole of the equatorial plane.

**Task 7:**

Mark the position of the poles of the pressure (**P**) and tension axes (**T**) on the equatorial plane and determine the direction of these axes towards (for **P**) and away from the center (for **T**) of the used net (see Figure 6). The poles for **P** and **T** lie on the equatorial plane in the center of the respective quadrants of downward (– or **o**) and upward (+) P-wave first motions, i.e., 45° away from the intersection points of the two fault planes with the equatorial plane. **Note:**

**All angles in the net projections have to be measured along great circles!**

**Task 8:**

Mark the slip vectors, connecting the intersection points of the fault planes with the equatorial plane, with the center of the considered net. If the center lies in a tension quadrant, then the slip vector points either from P2 on FP1 or from P1 on FP2 to the net center (see Figure 6). If it lies in a pressure quadrant, then the slip vectors points from the center in the opposite directions. The **slip vector** shows the direction of displacement of the **hanging wall** (see Figure 5).

**Task 9:**

Determine the azimuth (fault strike direction  $\phi_s$ ) of both FP1 and FP2. It is the angle measured clockwise against North between the directional vector connecting the center of the net with the end point of the respective projected fault trace lying towards the right of the net center (i.e., with the fault plane dipping towards the right; see Figure 6).

**Task 10:**

Determine the dip angle  $\delta$  (measured from horizontal) for both FP1 and FP2 by putting their projected traces on a great circle. Measure  $\delta$  as the difference angle from the outermost great circle (perimeter of the net) towards the considered fault-plane trace.

**Task 11:**

Determine the slip direction (i.e., the sense of motion along the two possible fault planes. It is obtained by drawing one vector each from the center of the net to the poles P1 and P2 of the nodal planes (or vice versa from the poles to the center, depending on the sign of the rake angle  $\lambda$ ). The vector from (or to) the center towards (or away from) P1 (P2) shows the slip direction along either FP2 or FP1. The **rake angle**  $\lambda$  is **negative** when it lies in the pressure (–) quadrant (event **with a normal faulting component**) and **positive** in case the center of the net lies in the tension (+) quadrant (i.e., an **event with a thrust component**) (Figure 7 top). In the first case holds  $\lambda = -\lambda^*$  and in the second case  $\lambda = 180^\circ - \lambda^*$ .  $\lambda^*$  has to be measured on the great circle of the respective fault plane between its crossing point with the equatorial plain and the respective azimuth direction of the considered fault plane (see Figure 6). For a pure strike slip motion ( $\delta = 90^\circ$ )  $\lambda = 0$  defines a left lateral strike-slip and  $\lambda = 180^\circ$  defines a right-

lateral strike-slip which can also be interpreted as a left-lateral (counter-clockwise) or right-lateral (clockwise) “rotational” movement of the two blocks against each other (Figure 7 below). **Note:** If the slip on the first fault plane is left-lateral the slip on the second one is right-lateral and vice versa.

**Figure 7** Basic types of earthquake faulting for some selected dip and rake angles. Mixed types of faulting occur when  $\lambda \neq 0, 180^\circ$  or  $\pm 90^\circ$ , e.g., normal faulting with strike-slip component or strike-slip with thrust component. Also, dip angles may vary between  $0^\circ < \delta \leq 90^\circ$ . For fault-plane traces and polarity distributions of mixed faulting types in their "beach-ball presentation" see also Chapter 3, section Fault-plane solutions.

#### Task 12:

The azimuth of the pressure and the tension axes, respectively, is equal to the azimuth of the line connecting the center of the net through the poles of **P** and **T** with the perimeter of the net. Their plunge is the dip angle of these vectors against the horizontal (to be measured as for  $\delta$ ) (see Figure 6).

#### Task 13:

Insert your results of estimated fault-plane parameters as well as pressure and tension axes for the Erzincan aftershock into Table 2.

**Table 2**

|                      | strike | dip | rake |
|----------------------|--------|-----|------|
| <b>Fault plane 1</b> |        |     |      |
| <b>Fault plane 2</b> |        |     |      |

|               | azimuth | plunge |
|---------------|---------|--------|
| Pressure axis |         |        |
| Tension axis  |         |        |

**Note:** The angles may range between:

$$\begin{aligned}
 0^\circ &< \text{strike} < 360^\circ \\
 0^\circ &< \text{azimuth} < 360^\circ \\
 0^\circ &< \text{dip} < 90^\circ \\
 0^\circ &< \text{plunge} < 90^\circ \\
 -180^\circ &< \text{rake} < 180^\circ
 \end{aligned}$$

#### Task 14:

The question which of the two nodal planes was the active fault plane, and hence the other the auxiliary plane, cannot be answered on the basis of the fault-plane solution alone. Considering the event in its seismotectonic context may give an answer. Therefore, we have marked the epicenter of the event in Figure 8 with an open star at the secondary fault F2 to the North Anatolian Fault (NAF).

**Figure 7** Epicenters of aftershocks between March 21 and June 16, 1992 of the March 13, 1992 Erzincan earthquake, Turkey. The open circles represent the main shock (blue) and its strongest aftershock on March 15 (green), and the red star the analyzed aftershock. **F1, F2 and F3** are secondary faults to the North Anatolian Fault (NAF). **Black arrows** - directions of relative plate motion, **open arrows** - direction of maximum horizontal compression as derived from centroid moment-tensor solutions of stronger earthquakes (modified Figure from Grosser et al., 1998).

- Decide which was the likely fault plane (FP1 or FP2)?
- What was the type of faulting?
- What was the direction of slip? and
- Is your solution compatible with the general sense of plate motion in the area as well with the orientation of the acting fault and the orientation of stress/deformation in the area?

## 4 Solutions and discussion

Taking it that you have carried out the exercise step-by-step yourself according to the above data, tasks and explanations, you may now compare your results, again step-by-step, with those which the authors of this exercise derived themselves by hand and or plotted them by using a computer program. The PC derived values are given in the summary parameter table in brackets. Fault planes determined by eye-fit to the polarity data may be uncertain by about  $\pm 10^\circ$ . This is acceptable. Even computer-assisted best fits to the data will produce different acceptable solutions within about the same error range with only slightly different standard deviations (e.g., Figure 1 in EX 3.3, comparing NEIC and HRVD solutions, respectively). But poor distribution of seismological stations (resulting in insufficient polarity data in several quadrants of the net diagram), erroneous polarity readings and/or differences in the velocity models used may result in still larger deviations between calculated and actual fault planes. One should also be aware that the assumed constant angular ( $45^\circ$ ) relationship between the fault plane on the one hand and the pressure and tension axis on the other hand is true in fact only in the case of a fresh rupture in a homogeneous isotropic medium. It may not be correct in the stress environment of real tectonic situations and for near surface sources in particular (i.e.,  $P$  and  $T \neq \sigma_1$  and  $-\sigma_3$ , respectively; see discussion in section 3.1.2.6 of Chapter 3). Only the parameters of the fault plane are relatively reliable, provided that this applies also to the used velocity model. If, however, your polarity patterns and/or manually determined parameter values differ by more than about  $20^\circ$  from the solutions presented below or yield even a different type of faulting mechanism then you should critically check and correct your data entries and/or fault-plane fits.

### Solution 1, Task 1:

| STA | AZM<br>(degree) | $\Theta$<br>(degree) | POL | AZMc<br>(degree) | $\Theta_c$<br>(degree) |
|-----|-----------------|----------------------|-----|------------------|------------------------|
| ALI | 40              | 130                  | D   | 220              | 50                     |

**Solutions 2, Tasks 3-5, 9 and 10: Plotting polarities, finding FP1 and determining its strike and dip.** Note that FP1 goes through a cluster of nearby conflicting polarities but separates well most of the + and - (•) signs.

**Solution 3, Task 6, 9 and 10: Finding FP2 and determining its strike and dip.**

**Solution 3, Task 7: Position of the poles on the equatorial plane EP of the pressure axis P (green) and tension axis T (red):**

**Solutions 4, Tasks 8, 11 and 12: Drawing the slip vectors of FP1 and FP2, determining the rake angle and measuring the azimuth and plunge of the P and T axes.**

### Summary solutions of all tasks:

Table 3 summarizes both the angles measured by hand as well as the ones (in brackets) that result from best fitting computer analysis of the polarity plots. The agreement is astonishingly good.

**Table 3**

|                            | strike        | dip         | rake          |
|----------------------------|---------------|-------------|---------------|
| <b>Fault plane1 (FP1)</b>  | 280° (278.5°) | 40° (39.9°) | 68° (67.4°)   |
| <b>Fault plane 2 (FP2)</b> | 130° (127.0°) | 54° (53.7°) | 108° (107.8°) |

|                      | azimuth       | plunge      |
|----------------------|---------------|-------------|
| <b>Pressure axis</b> | 205° (204.4°) | 7° (7.1°)   |
| <b>Tension axis</b>  | 90° (88.6°)   | 73° (74.0°) |

### Solution 5, Task 14:

- FP2 was more likely the active fault.
- The aftershock was a thrust event with a very small right-lateral strike-slip component.

- c) The slip direction is here strike - rake azimuth, i.e., for FP2  $130^\circ - 108^\circ = 12^\circ$  from north. This is close to the direction of maximum horizontal compression ( $15^\circ$ ) in the nearby area as derived from centroid moment-tensor solutions of stronger events.
- d) The strike of FP2 for this event agrees quite well with the strike direction of mapped local faults F1, F2, and F3 in the horse tail formed aftershock cloud southeast of the Erzincan basin. The strongest aftershock ( $M_s = 5.8$ ) on March 15, 1992 (small double circles) took place in the horse tail part, too. Therefore, it is probable that FP2 was the acting fault. The North Anatolian Fault (NAF) which reflects the general tectonics confines the northern margin of the aftershock zone and it is continuing towards the triple point of the NAF with the East Anatolian Fault.

## 1 Aim

The exercise aims at making familiar with the calculation of the take-off angles AIN of seismic P-wave rays leaving the seismic source towards the seismic station. These angles are required for determining fault-plane solutions (FPS) from first-motion polarity readings (see EX 3.2). Take-off angles depend on the velocity model of the Earth, the source depth  $h$  and the epicentral distance  $\Delta$ , at which the considered rays arrive at the Earth's surface. The AIN calculated in this exercise for a given event and a number of seismic stations at different  $\Delta$  will then be checked whether they are consistent with the reported polarity readings and FPS calculated for this event by international agencies. For this you will reconstruct on a Lambert-Schmidt net projection the fault-plane traces from the reported nodal-plane parameters.

## 2 Data, models and procedure

When localizing near events by using HYPO71 or similar programs the values for both the azimuth (AZM) and for the take-off angles (AIN) of the rays leaving the source towards the considered stations are given in the localization output file. One can use them, together with the first motion polarity readings, straight forward for the determination of fault-plane solutions (see EX 3.2). When one intends to determine the fault-plane solution for seismic events published in the bulletins of the International Seismological Centre (ISC) one finds therein, besides data for polarity readings from the reporting stations ( $\uparrow$  or  $c$  for up and  $\downarrow$  or  $d$  for down in short- or long-period instruments, respectively), only values for the azimuth (AZM) but not for the respective take-off angle (AIN). Figure 1 shows a typical portion of event-stations report from the ISC. Its header also gives the seismic moment tensor and fault-plane solutions calculated by various international data centers or agencies using different (sometimes automated) procedures. Values for AIN can be calculated by using the relationship

$$\sin \text{AIN} = (180/\pi) \times (v_p/r_h) \times p(\Delta, h). \quad (1)$$

$v_p(h)$  is the P-wave velocity at the depth  $h$  (in km/s),  $r_o = 6371$  km is the Earth's radius and  $r_h = r_o - h$ .  $p(\Delta, h) = dT/d\Delta$  is the ray parameter; it corresponds to the gradient of the travel-time curve at the point of observation on the Earth's surface (both in units s/deg) at the epicentral distance  $\Delta$  (in degree) (see Fig. 2.27) and is a function of the hypocentral depth  $h$  (in km). The value of the ray parameter is identical with that of the horizontal component of the of the slowness vector. Tables 1 and 2 give the respective values  $v_p(h)$  and  $p(\Delta, h)$  for P waves.

**Table 1**  $v_p(h)$  according to the IASPEI91 velocity model (Kennett, 1991).

| h (km) | $v_p$ (km/s) | h (km) | $v_p$ (km/s) | h (km) | $v_p$ (km/s) |
|--------|--------------|--------|--------------|--------|--------------|
| 0      | 5.8000       | 120    | 8.0500       | 471    | 9.5650       |
| 20     | 5.8000       | 171    | 8.1917       | 571    | 9.9010       |
| 20     | 6.5000       | 210    | 8.3000       | 660    | 10.2000      |
| 35     | 6.5000       | 271    | 8.5227       | 660    | 10.7900      |
| 35     | 8.0400       | 371    | 8.8877       | 671    | 10.8192      |

**Figure 1** Typical section of an ISC bulletin (left) with NEIC (National Earthquake Information Center) and Harvard University (HRVD) moment-tensor fault-plane solutions (right) for the Italy deep earthquake ( $h = 286$  km) of Jan. 05, 1994. Columns 3 to 5 of the bulletin give the following data: 3 - epicentral distance in degrees, 4 - azimuth AZM in degrees, 5 - phase code and polarity.

Table 3 gives respective selected data from the ISC bulletin for five seismic stations at different epicentral distances ( $\Delta$ ) and azimuth (AZM) for the Italy earthquake shown in Figure 1. The polarity readings correspond to the first P ( $\Delta < 100^\circ$ ) or PKP ( $\Delta > 110^\circ$ ) onsets.

### 3 Tasks

#### Task 1:

For the data given in Table 3, calculate the missing values in the blank columns for  $v_p(h)$ ,  $v_p/r_h$ ,  $p(\Delta, h)$  and AIN using Table 1 and 2 and assuming an approximate focal depth for the recorded event of  $h = 300$  km. Interpolate linearly as a first approximation.

#### Task 2:

Decide whether your ray has left the upper or lower half of the focal sphere and whether or not you need to calculate AINc and/or AZMc according to Figs. 3.28 and 3.29 in Chapter 3. Complete Table 3 accordingly.

#### Task 3:

Use the values given in Figure 1 for  $\phi$  and  $\delta$  for the nodal planes NP1 and NP2 of the NEIC fault-plane solution. Reconstruct both nodal (fault) planes using the *Lambert-Schmidt net* (Fig. 3.27b) by applying the procedure inverse to the one described in the Exercise : Determination of fault-plane solutions (EX 3.2). Compare your nodal-plane pattern with that of the NEIC "beach-ball" solution (Figure 1 upper right).

#### Task 4:

Find the corresponding equatorial plane to your NP1 and NP2 and mark the locations of the P and T axes on the focal sphere. Draw the P and T vectors towards and from the center of the net, determine their azimuth (Azm) and plunge (Plg) [equivalent to dip, measured from the horizontal]. Compare your respective values with those given by NEIC in Figure 1.

#### Task 5:

Use the values that you calculated for the P-wave take-off angle AINc and ray azimuth AZMc to all 5 stations in Table 3 and mark the point where the ray penetrates the focal sphere and indicate the respective polarity. Check whether they fall into the proper T and P quadrants and whether the short-period polarity readings given in Table 3 are consistent with the fault-plane solution published by the NEIC which is based on long-period waveform data.

### 4 Solutions and discussions

**Table 4** Solutions for Task 1.

| STA | $\Delta$<br>(deg) | AZM<br>(deg) | POL | $v_p(h)$<br>km/s | $v_p/r_h$<br>(s <sup>-1</sup> ) | $p(\Delta, h)$<br>(s/deg) | AIN<br>(deg) | AZMc<br>(deg) | AINc<br>(deg) |
|-----|-------------------|--------------|-----|------------------|---------------------------------|---------------------------|--------------|---------------|---------------|
| SGG | 2.30              | 345          | +   | 8.6286           | $1.4213 \times 10^{-3}$         | 8.368                     | (137.0)      | 165           | 43.0          |
| KHC | 10.03             | 354          | -   |                  |                                 | 12.258                    | 86.5         |               |               |
| BTH | 12.25             | 294          | +   |                  |                                 | 11.984                    | 77.4.1       |               |               |
| ZAK | 60.02             | 48           | -   |                  |                                 | 6.759                     | 33.4         |               |               |
| PAE | 154.8             | 324          | -   |                  |                                 | 1.368                     | 6.4          |               |               |

**Task 2:**

**Note:** In the case of deep earthquakes the values of the ray parameter (and thus slowness) may increase with  $\Delta$ , e.g., in Table 2 for  $h = 300$  km up to  $\Delta = 10^\circ$ . This corresponds to seismic rays that leave the source upwards! Consequently, the value  $AIN = 43.0^\circ$  calculated with Equation (1) for station SGG corresponds, according to the definition given in Fig. 3.28, in fact to an angle of  $180^\circ - AIN = 137.0^\circ$ . Accordingly,  $AZMc$  and  $AINc$  for the equivalent lower hemisphere projection of this ray are  $345^\circ - 180^\circ = 165^\circ$  and  $43.0^\circ$ , respectively.

**Task 3:**

Your manually drawn fault-plane solutions should look very similar to that of the NEIC solution in Figure 1 upper right.

**Task 4:**

Your manually re-constructed values for  $Azm$  and  $Plg$  of the P and T axes should agree with the NEIC solution within a few degrees ( $<10^\circ$ ). If not, check your drawing of the three planes, of the related P and T axis and the measured angles.

**Task 5:**

The short-period polarity data used in this exercise are consistent with the fault-plane solution published by the NEIC which is based on long-period waveform data. All your polarities should fall properly into quadrants of either observed compressional or dilatational P-wave first motions.

## 1 Aim

This exercise shows how to estimate the source parameters seismic moment, size of the rupture plane, source dislocation and stress drop from data in the frequency domain only and how the results depend on the underlying model assumptions. These parameters could also be estimated in the time domain. However, for estimation in the time domain the records have to be converted into true ground motion (displacement) records. This may be a problem if the bandwidth of the recording system is limited (e.g., short-period records) or if the phase response of the system is not well known. For estimation in the frequency domain only the amplitude response of the instrument is needed.

## 2 Data

Figure 1 shows a velocity record (vertical component) of an aftershock of the 1992 Erzincan earthquake (Turkey). Figure 2 shows the corresponding *displacement spectrum* of the P wave. The calculated spectrum was corrected for the amplitude response of the recording system (which includes both response of the velocity seismometer and the anti-aliasing filter of the recorder). Furthermore, the P-wave spectrum was corrected for attenuation,  $\exp(i\omega t/2Q_p)$ .  $Q_p$  had been estimated beforehand from coda  $Q_c$ - observations in the area under study assuming that  $Q_p = 2.25 Q_c$ . This is a good approximation under the assumption that  $v_p/v_s = 1.73$ ,  $Q_c = Q_s$  and the pure compressional  $Q_\kappa$  ( $\kappa$  - bulk modulus) is very large ( $\rightarrow \infty$ ). In Figure 2 also the noise spectrum, treated in the same way as the P-wave spectrum, was computed and plotted in order to select the suitable frequency range for analysis (with signal-to-noise ratio  $SNR > 3$ ).

At low frequencies typical P- and S-wave spectra approach a constant amplitude level  $u_0$  and at high frequencies the spectra show a decay that falls off as  $f^{-2}$  to  $f^{-3}$ . Plotted on a log-log scale the spectrum can be approximated by two straight lines. The intersection point is the corner frequency  $f_c$ .  $u_0$  and  $f_c$  are the basic spectral data from which the source parameters will be estimated. Event and material data required for further calculations are the epicentral distance  $\Delta$ , the source depth  $h$ , the rock density  $\rho$ , the P-wave velocity  $v_p$ , and the averaged radiation pattern  $\Theta$  for P waves. Respective values are given under 3.1 below. Other needed parameters can then be calculated.

**Note:** The apparent increase of spectral noise amplitudes in Figure 2 for  $f > 25$  Hz and of signal amplitudes for  $f > 50$  Hz is not real but sampling noise due to anti-aliasing filtering of the record. Thus, this increase should not be considered in the following analysis. The same

holds for spectral amplitudes  $f < 1$  Hz. Since the analyzed P-wave train is only 2 s long, lower frequencies are not properly represented.

**Figure 1** Record of an Erzincan aftershock (vertical component). For the indicated P-wave window the displacement spectrum shown in Figure 2 has been calculated.

**Figure 2** P-wave spectrum (upper curve) and noise spectrum (lower curve) of the record shown in Figure 1, corrected for the instrument response and attenuation.

### 3 Procedures

The parameters to be estimated are:

- Seismic moment  $M_0 = \mu \bar{D} A$  (1)  
(with  $\mu$  - shear modulus;  $\bar{D}$  - average source dislocation;  $A$  - size of the rupture plane)
- Source dislocation  $\bar{D}$
- Source dimension (radius  $R$  and area  $A$ )
- Stress drop  $\Delta\sigma$

#### 3.1 Seismic moment $M_0$

Under the assumption of a homogeneous Earth model and constant P-wave velocity  $v_p$ , the seismic moment  $M_0$  can be determined from the relationship:

$$M_0 = 4 \pi r v_p^3 \rho u_0 / (\Theta S_a) \quad (2)$$

with  $r$  – hypocentral distance,  $\rho$  - density,  $u_0$  – low-frequency level (plateau) of the displacement spectrum,  $\Theta$  - average radiation pattern and  $S_a$  surface amplification for P waves.

In the exercise we use the following values: density

$$\rho = 2.7 \text{ g/cm}^3$$

P-wave velocity

$$v_p = 6 \text{ km/sec}$$

source depth

$$h = 11.3 \text{ km}$$

epicentral distance

$$\Delta = 18.0 \text{ km}$$

hypocentral distance  
(travel path)

$$r = \sqrt{(h^2 + \Delta^2)}$$

incidence angle

$$i = \arccos(h/r)$$

free surface amplification  $S_a$  for P waves

averaged radiation pattern  $\Theta = 0.64$  for P waves.

**Note** the differences in dimensions used!  $M_0$  has to be expressed in the unit  $\text{Nm} = \text{kg m}^2 \text{s}^{-2}$ .  $S_a$  can be determined by linear interpolation between the values given in Table 1. They were computed for the above given constant values of  $v_p$  and  $\rho$  (homogeneous model) and assuming a ratio  $v_p/v_s = 1.73$ .  $i$  is the angle of incidence, measured from the vertical.

**Table 1** Surface amplification  $S_a$  for P waves;  $i$  is the incidence angle.

| $i$ | $S_a$ | $i$ | $S_a$ | $i$ | $S_a$ |
|-----|-------|-----|-------|-----|-------|
| 0   | 2.00  | 30  | 1.70  | 60  | 1.02  |
| 5   | 1.99  | 35  | 1.60  | 65  | 0.90  |
| 10  | 1.96  | 40  | 1.49  | 70  | 0.79  |
| 15  | 1.92  | 45  | 1.38  | 75  | 0.67  |

|    |      |    |      |    |      |
|----|------|----|------|----|------|
| 20 | 1.86 | 50 | 1.26 | 80 | 0.54 |
| 25 | 1.79 | 55 | 1.14 | 85 | 0.35 |

### 3.2 Size of the rupture plane

For estimating the size of the rupture plane and the source dislocation one has to adopt a kinematic (geometrical) model, describing the rupture propagation and the geometrical shape of the rupture area. In this exercise computations are made for three different circular models (see Table 2), which differ in the source time function and the crack velocity  $v_{cr}$ .  $v_s$  is the S-wave velocity, which is commonly assumed to be  $v_s = v_p / \sqrt{3}$ .

**Table 2** Parameters of some commonly used kinematic rupture models.

|                        |                    |              |              |
|------------------------|--------------------|--------------|--------------|
| 1. Brune (1970)        | $v_{cr} = 0.9 V_s$ | $K_p = 3.36$ | $K_s = 2.34$ |
| 2. Madariaga I (1976)  | $v_{cr} = 0.6 V_s$ | $K_p = 1.88$ | $K_s = 1.32$ |
| 3. Madariaga II (1976) | $v_{cr} = 0.9 V_s$ | $K_p = 2.07$ | $K_s = 1.38$ |

The source radius  $R$  (in km) can then be computed from the relationship

$$R = v_s K_{p/s} / 2\pi f_{c_{p/s}} \quad (3)$$

with  $v_s$  – shear-wave velocity in km/s,  $f_{c_{p/s}}$  – corner frequency of the P or S waves, respectively, in Hz and  $K_p$  and  $K_s$  being the related model constants and  $v_s$ . The differences in  $K_p$  and  $K_s$  between the various models are due to different assumptions with respect to crack velocity and the rise time of the source-time function. Only  $K_p$  has to be used in the exercise (P-wave record!). The size of the circular rupture plane is then

$$A = \pi R^2. \quad (4)$$

### 3.3 Average source dislocation $\bar{D}$

According to (1) the average source dislocation is

$$\bar{D} = M_0 / (\mu A). \quad (5)$$

Assuming  $v_s = v_p / 1.73$  it can be computed knowing  $M_0$ , the source area  $A$  and the shear modulus  $\mu = v_s^2 \rho$ .

### 3.4 Stress drop

The static stress drop  $\Delta\sigma$  describes the difference in shear stress on the fault plane before and after the slip. According to Keilis-Borok (1959) the following relationship holds for a circular crack with a homogeneous stress drop:

$$\Delta\sigma = 7 M_0 / (16 R^3). \quad (6)$$

The stress drop is expressed in the unit of Pascal,  $\text{Pa} = \text{N m}^{-2} = \text{kg m}^{-1} \text{s}^{-2} = 10^{-5} \text{ bar}$ .

## 4 Tasks

### Task 1:

Select in Figure 2 the frequency range  $f_1$  to  $f_2$  that can be used for analysis ( $\text{SNR} > 3$ ):

$$f_1 = \dots\dots\dots \text{ Hz}$$

$$f_2 = \dots\dots\dots \text{ Hz}$$

### Task 2:

Estimate the low-frequency level,  $u_o$ , of the spectrum by approximating it with a horizontal line. Note in Figure 2 the logarithmic scales and that the ordinate dimension is  $\text{nm s} = 10^{-9} \text{ m s}$ .

$$u_o = \dots\dots\dots \text{ m s}$$

### Task 3:

Estimate the exponent,  $n$ , of the high-frequency decay,  $f^{-n}$ ; mark it by an inclined straight line.

$$n = \dots\dots\dots$$

### Task 4:

Estimate the corner frequency,  $f_{c_p}$  (the intersection between the two drawn straight lines).

$$f_{c_p} = \dots\dots\dots \text{ Hz}$$

### Task 5:

Calculate from the given event parameters and relationships given in 3.1 and Table 1 the values for:

$$r = \dots\dots\dots \text{ km}$$

$$i = \dots\dots\dots^\circ$$

$$S_a = \dots\dots\dots$$

$$M_o = \dots\dots\dots \text{ Nm.}$$

### Task 6:

Using the equations (3), (4), (5) and (6) calculate for the three circular source models given in Table 2 the parameters

- source radius  $R$  and source area  $A$ ,
- shear modulus  $\mu$  and average displacement  $\bar{D}$  and
- stress drop  $\Delta\sigma$ .

Write the respective values in Table 3

**Table 3**

| Model          | $R$ [m] | $A$ [m <sup>2</sup> ] | $\bar{D}$ [m] | $\Delta\sigma$ [MPa] |
|----------------|---------|-----------------------|---------------|----------------------|
| 1. Brune       |         |                       |               |                      |
| 2. Madariaga I |         |                       |               |                      |

3. Madariaga II

## 5 Solutions

Although individual visual parameter readings from Figure 2 might be subjective, they should not differ by more than about  $\pm 10\%$  from the values given here for tasks 1 to 5 but may be larger for 6. Acceptable average values for the read and calculated parameters are for:

**Task 1:**  $f_1 = 2 \text{ Hz}$ ,  $f_2 = 30 \text{ Hz}$

**Task 2:**  $u_o = 3 \times 10^{-7} \text{ m s}$

**Task 3:**  $n = 3$

**Task 4:**  $f_{cp} = 14.4 \text{ Hz}$

**Task 5:**  $r = 21.3 \text{ km}$   $i = 58^\circ$ ,  $S_a = 1.07$ ,  $M_o = 6.8 \times 10^{13} \text{ N m}$

**Task 6:**

a)  $R_1 = 129 \text{ m}$ ,  $A_1 = 5.23 \times 10^4 \text{ m}^2$   
 $R_2 = 72 \text{ m}$ ,  $A_2 = 1.63 \times 10^4 \text{ m}^2$   
 $R_3 = 79 \text{ m}$ ,  $A_3 = 1.96 \times 10^4 \text{ m}^2$

- b)  $\mu = 3.24 \times 10^{10} \text{ kg m}^{-1} \text{ s}^{-2}$   $D_1 = 4.0 \times 10^{-2} \text{ m}$   
 $D_2 = 1.3 \times 10^{-1} \text{ m}$   
 $D_3 = 1.1 \times 10^{-1} \text{ m}$
- c)  $\Delta\sigma_1 = 13.8 \text{ MPa}$   
 $\Delta\sigma_2 = 79.7 \text{ MPa}$   
 $\Delta\sigma_3 = 60.3 \text{ MPa}$

## 6 Comments

One should always be aware that the interpretation of seismic source spectra is based on simplified model assumptions of the generally unknown *source geometry* (e.g., circular fault or rectangular fault with different, also magnitude dependent aspect ratios), as well as unknown *rupture kinematics* (rupture velocity and direction, e.g. uni- and/or bilateral and – directional; see Figure 6 in IS 3.1), and *dynamics* (stress drop). Different model assumption will yield different results, even for identical spectral parameter readings, as demonstrated with the above solutions. They may differ even for the most common models of small earthquakes by a factor of about two for the source “radius” and more than 5 for the stress drop (because of  $\Delta\sigma \sim R^{-3}$ ).

Moreover, also the correction of measured spectra for wave propagation effects (geometric spreading, scattering and intrinsic attenuation) is largely model-based and thus error-prone. And the reading from rather noisy empirical spectra of the spectral plateau amplitude - and in particular of the corner frequency - is afflicted with relatively large errors too. All this increases further the uncertainty of source radius and especially stress-drop estimates. The latter may be, in the worst case, uncertain up to about two orders of magnitude.

Therefore, in studying possible systematic differences in source parameters derived from spectral data for events in a given area, or within an aftershock sequence, one should always stick to using one type of model only, even if this might not be the best in absolute terms with respect to the given (but usually not yet well known) specific seismotectonic situation. Yet, one should at least be reasonably sure about the validity of assuming that the events have similar modes of faulting and crack propagation. If later models become available which better seem to describe the seismic source processes in the area and/or in the magnitude range under investigation then earlier, maybe inferior but consistent results, may be “rescaled”.

## 1 Aim

The tasks in this exercise are aimed at making you more familiar with the use and meaning of the basic equations and matrix formalisms in seismic moment-tensor presentation and decomposition.

## 2 Formulae used

The following formulae are used:

$$d_s(x, t) = M_{kj} [G_{skj}(x, \xi, t) * s(t)] \quad (1)$$

which is identical with Eq. (3.70) in Chapter 3, with  $d_s(x, t)$  - ground displacement at position  $x$  and time  $t$ . (1) simplifies to  $d_s(x, t) = M_{kj} G_{skj}(t)$  if the source-time function  $s(t) = \delta(t)$  is a needle (spike) impulse.

$$M_{kj} = A \{ \Lambda v_i s_i \delta_{kj} + \mu (v_k s_j + v_j s_k) \} \quad (2)$$

which describes the seismic moment tensor for an isotropic medium in the most general way with  $\Lambda$  - elastic Lamé-parameter,  $\mu$  - shear modulus,  $A$  - area of fault rupture,  $s$  - slip vector on the fault and  $v$  - normal to the fault plane. Note that the scalar seismic moment  $M_0 = \mu A |s|$ . The term  $(v_k s_j + v_j s_k)$  forms a tensor  $D$  describing a double-couple source. In case of an explosion it is zero. And the equations:

$$\begin{aligned}
 M_{xx} &= -M_0(\sin\delta \cos\lambda \sin 2\phi + \sin 2\delta \sin\lambda \sin^2\phi) \\
 M_{xy} &= M_0(\sin\delta \cos\lambda \cos 2\phi + 0.5 \sin 2\delta \sin\lambda \sin 2\phi) \\
 M_{xz} &= -M_0(\cos\delta \cos\lambda \cos\phi + \cos 2\delta \sin\lambda \sin\phi) \\
 M_{yy} &= M_0(\sin\delta \cos\lambda \sin 2\phi - \sin 2\delta \sin\lambda \cos^2\phi) \\
 M_{yz} &= -M_0(\cos\delta \cos\lambda \sin\phi - \cos 2\delta \sin\lambda \cos\phi) \\
 M_{zz} &= M_0 \sin 2\delta \sin\lambda
 \end{aligned} \quad (3)$$

with  $\phi$  - strike direction and  $\delta$  - dip angle of the rupture plane, and  $\lambda$  - slip direction (rake angle).

### 3 Tasks

**Task 1:**

By using Equations (2) and (3) above, respectively, determine the Cartesian moment tensors for:

- a) an underground nuclear explosion;
- b) a double-couple focal mechanism with strike  $\phi = 0^\circ$ , dip  $\delta = 90^\circ$ , and rake  $\lambda = 0^\circ$ ;
- c) a double-couple focal mechanism with  $\phi = 0^\circ$ ,  $\delta = 45^\circ$ , and  $\lambda = 90^\circ$ ;
- d) a double-couple focal mechanism with  $\phi = 0^\circ$ ,  $\delta = 90^\circ$ , and  $\lambda = 90^\circ$ .

**Task 2:**

Determine the moment tensor for a tension crack in the direction normal to the fault plane in a homogenous isotropic medium. Use Equation (2) of the exercise.

**Task 3:**

The relation Equation (3) between moment tensor and parameters of a shear dislocation can be expressed as a weighted sum of 4 elementary moment tensors:

$$M = \cos\delta \cos\lambda M_1 + \sin\delta \cos\lambda M_2 - \cos 2\delta \sin\lambda M_3 + \sin 2\delta \sin\lambda M_4.$$

Derive the elements of  $M_1$ ,  $M_2$ ,  $M_3$ , and  $M_4$  and discuss the shear dislocations that are represented by the elementary moment tensors.

### 4 Solutions

**Task 1:**

$$\text{a) } M = M_0 \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$\text{b) } M = M_0 \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\text{c) } M = M_0 \begin{pmatrix} 0 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$\text{d) } M = M_0 \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{pmatrix}$$

**Task 2:**

$$M = \begin{pmatrix} \Lambda s_3 & 0 & 0 \\ 0 & \Lambda s_3 & 0 \\ 0 & 0 & (\Lambda + 2\mu)s_3 \end{pmatrix}$$

**Task 3:**

$$M_1 = M_0 \begin{pmatrix} 0 & 0 & -\cos\phi \\ 0 & 0 & -\sin\phi \\ -\cos\phi & -\sin\phi & 0 \end{pmatrix} \rightarrow \delta = 0^\circ; \lambda = 0^\circ, \text{ i.e., horizontal slip on horizontal fault}$$

$$M_2 = M_0 \begin{pmatrix} -\sin 2\phi & \cos 2\phi & 0 \\ \cos 2\phi & \sin 2\phi & 0 \\ 0 & 0 & 0 \end{pmatrix} \rightarrow \delta = 90^\circ; \lambda = 0^\circ, \text{ i.e., strike slip on vertical fault}$$

$$M_3 = M_0 \begin{pmatrix} 0 & 0 & \sin\phi \\ 0 & 0 & -\cos\phi \\ \sin\phi & -\cos\phi & 0 \end{pmatrix} \rightarrow \delta = 90^\circ; \lambda = 90^\circ, \text{ i.e., dip slip on a vertical fault}$$

$$M_4 = M_0 \begin{pmatrix} -\sin^2\phi & \frac{1}{2}\sin 2\phi & 0 \\ \frac{1}{2}\sin 2\phi & -\cos^2\phi & 0 \\ 0 & 0 & 1 \end{pmatrix} \rightarrow \delta = 45^\circ; \lambda = 90^\circ, \text{ i.e. dip slip on a } 45^\circ \text{ dipping fault.}$$

| Title   | A practical on moment tensor inversion using the Kiwi tools                                                                                                                                                                                                                                                                                                                                                             |

## 1 Introduction

This tutorial with exercises introduces to the use of the Kiwi tools (Heimann, 2011; Cesca et al., 2010), an open source seismological software developed at the University of Hamburg and the GFZ Potsdam for the goal of moment tensor inversion and finite source inversion. The following text is accompanied by an electronic supplement, including a virtual machine (KiwiVirtualBox) with a Linux Ubuntu system. The virtual machine includes all required software, manuals, and data examples here discussed. It can be downloaded at [10.5880/GFZ.2.1.2013.001](https://doi.org/10.5880/GFZ.2.1.2013.001).

The aim is to guide the reader through the different modules required to perform a moment tensor inversion. All moment tensor and source inversion routines in seismology require access to the following components: Green's functions, seismological data, inversion framework and results assessment.

The following sections introduce the reader to the Kiwi tools devoted to the Green's function databases handling, data access and visualization, selection of the inversion parameters and inversion process, and results visualization. While describing the most important software tools and their more relevant options, specific examples guide the reader through the different steps of the inversion process. In conclusion, a number of relevant exercises are provided.

## 2 Green's functions

Green's functions (GFs) describe, on the basis of model assumptions or empirically gained data, the wave propagation from the seismic source to a receiver, in response to specific source excitation. In the framework of source inversion problems, they are used to build synthetic seismograms, which are compared to real surface data records in the moment tensor inversion.

In the current setup of the Kiwi tools, only 1D velocity models are considered. This means, Earth models for which all relevant properties (P and S wave velocities, density, attenuation coefficients) only change with depth. A 1D case presents certain advantages in terms of Green's function computation. First, several codes are nowadays freely available to solve the forward problem. Moreover, because of the symmetry of the model, it is only required to compute a limited number of Green's functions. For any combination of source depth and source-receiver distance, 10 Green's functions have to be computed. These 10 Green's

functions can be combined using proper weighting to compute the response to any moment tensor configuration at any azimuth.

Green's functions are typically stored into databases, which we refer here as Green's function database (GFDB). A GFDB may require a significant computational effort, but is then ready for use and significantly reduces computational time of the inversion. The Kiwi tools currently handle GFDB through HDF5 (the dependence on HDF5 may be removed in future Kiwi versions). The system is independent on the software used to generate GFs, however we have successfully worked so far with Qseis (Wang, 1999) and Gemini (Friedrich and Dalkolmo, 1995). GFDBs are built for any required velocity model with user-defined constraints. In particular, the following parameters have to be chosen when preparing a GFDB:

- Description of the velocity model,
- Range of epicentral distances,
- Range of source depths,
- GF sampling.

When preparing an own GFDB, these parameters have to be chosen carefully with respect to the area of study, network geometry, expected range of magnitudes and source depths, and sensor instrumentation (sampling rate, frequency range). The range of distances and depths limits the possible application of the GFDB, e.g. synthetic seismogram for too far away stations or too deep sources cannot be computed when exceeding the spatial boundary of a GFDB. Epicentral distances and depths should be sampled equidistant. The sampling interval limits the resolution potential of a GFDB: first, because it limits the maximal reproducible frequencies, and second because the inversion framework requires a common sampling of data and GFs.

The KiwiVirtualBox includes a single GFDB. This was generated with the software Qseis (Wang, 1999) for a global velocity model, IASP91 (Kennett & Engdahl, 1991). The available GFDB allows to build synthetic seismograms for sources down to 40 km and stations up to 1000 km epicentral distance with a spatial sampling of 1 km. Thus GFs are available every 1 km in distance and depth and the computation of synthetic seismograms in between grid points can either be done through GFs interpolation or by using the GFs of the closest grid point. The sampling is 0.5 s, so that the spectral fit cannot exceed 1 Hz.

The GFDB is found at the directory */GFDB*; its name is *GFDB/db*.

To get some information on the GFDB type:

*gfdb\_info GFDB/db*

In turn you get information on the sampling (dt), spatial GF sampling along epicentral distances and source depths (dx, dz), minimal epicentral distance and source depth (firstx, firstz), number of epicentral distances and source depths (nx, nz), number of GFs per source depth-epicentral distance geometry (ng, typically 10), and some additional technical information on the number of files used to allocate GFs (chunks) and the state of filling of a GFDB (for large GFDBs, with significant GF computation time, the available database may still be incomplete). Temporal and spatial units are always given in seconds and meters.

To extract a Green's function (in the example we extract from the database GFDB/db at a distance of 400000 m and source depth of 20000 m the GF number 1, and store it in the file `gf1.d400km.z20km.mseed`) in miniSEED format type (note that using a different extension than `.mseed` provides the GF in the default ASCII format):

```
gfdb_extract GFDB/db <<EOF
400000 20000 1 gf1.d400km.z20km.mseed
EOF
```

To view the Green's function with the snuffler visualizer type:

```
snuffler gf1.d400km.z20km.mseed
```

A new GFDB can be created using the Kiwi command `gfdb_build`, while a subset of an existing database can be created using the command `gfdb_redeploy`. Testing these commands with no argument, provide more information on their syntax:

```
gfdb_build
gfdb_redeploy
```

Further information on other Kiwi tools to generate and handle Green's function databases are available in the enclosed documentation (in the directory *DOCS*).

### 3 Data

The data, here intended as displacement waveforms, are an obvious prerequisite for any source inversion tool. Their characteristics, e.g., their sampling rate or the limited bandwidth of the flat displacement-proportional frequency response of the recording instrument can severely limit the inversion potential.

Kiwi can currently handle different formats, including the preferred miniSEED (see Chapter 10) and a simple ASCII format (first column time, second column displacement amplitude). Sampling should be common for any single study (e.g., for any treated earthquake case), and common to the adopted GFDB. Amplitudes are given in meters, times in seconds, with respect to the reference system timestamp, January 1, 1970, 00:00:00.

Data preprocessing is not described in detail here (see Scherbaum, 2007). However, displacement traces are typically obtained from velocity seismometers, through data recovery, tapering (see IS 14.1), removal of mean and trend and restitution to displacements, according to instrument response function. Data may also need to be converted to any of the usable data formats.

Displacement files for a single study (earthquake) should be stored in a single event directory, with the following naming:

```
DISPL.$STAT.$CHAN
```

where `$STAT` is the station code, and `$CHAN` the channel code (BHZ: Vertical, BHN: North, BHE: East, BHR: Radial, BHT: Transversal). The adoption of channel “BH” is only a naming convention, and does not limit the application of the Kiwi tools to any instrument type or channel.

The KiwiVirtualBox includes several datasets, which are described in the following paragraphs. All data are stored as miniSEED files, with a sampling of 0.5 s (common to the available GFDB). All data were recorded by velocity broadband sensors, and can be safely analyzed in any frequency band above 0.01 Hz and below 1 Hz.

An example of directory structure for a synthetic dataset can be found at:

```
DATA/SYNTH1
```

which is a synthetic example. Displacement waveforms have been created there for a pure double couple (DC) point source (location, and origin time are given in the last section), with the available GFDB and no noise (therefore they can be perfectly matched in the test inversion).

To visualize the typical content of a data directory type:

```
ls DATA/SYNTH1
```

It indicates files corresponding to displacement traces, plus an additional station file.

To look at the miniSEED waveforms, use the snuffler software:

```
snuffler DATA/SYNTH1/DISPL.*
```

The following command allows to include event information and to perform some data sorting:

```
snuffler DATA/SYNTH1/DISPL.* \  
--stations="META/stations.dat" --event="META/events.txt"
```

An event is then selected by typing “e” when the cursor is on the event label (a rectangle should appear around the label).

A left click on the event label opens a window with possible operations.

For example, it is possible to sort traces according to their epicentral distance from the selected event.

Repeating the operation with the following attribute allows to compare observed waveforms with synthetics for provided focal mechanisms.

```
snuffler DATA/SYNTH1/DISPL.* \  
--stations="META/stations.dat" --event="META/events_w_solutions.txt"
```

It is now possible to modify the frequency filter applied to both the recorded and the synthetic traces, and to visually inspect the effect of frequency filtering on both traces and on their fit.

Apart from the displacement files, the data directory includes one more file: *stations.dat*. This ASCII file, which can be opened with any text editor, is very important; the inversion cannot be performed without it. It include several lines, one per each desired station. Each line is composed by a station number (an increasing integer), the station code, latitude and longitude (in degrees).

Note that, when running the inversion and select a given station file, only stations listed in the station file and for which properly named traces are available in the data directory will be used. This implies that: (a) stations can be temporarily omitted, simply by file renaming (e.g.

removed.DISPL.STAT.BHZ), (b) several station files can be created, to simulate different network configurations, with no need to duplicate data.

## 4 Inversion setup

We refer to the inversion framework, in the most general sense, as to the combination of inversion software, scripts, input files and the selection of inversion parameters. In the general formulation of a source inversion process, the data and GFs have to be made accessible. Then, a source model is first considered, synthetic seismograms are computed on the basis of a selected source model and the adopted GFs, synthetic seismograms are then compared to observations, and a fit among data and synthetics is estimated. On the base of such a fit, the source model is modified, perturbed or “improved”, and the process iteratively repeated, until certain conditions are met. At the end of the process, the information regarding the best fitting model is released, typically together with amisfit estimation and suitable evaluation plots, such as the fault-plane (“beach-ball”) solution (see., e.g., section 3.4 of Chapter 3), waveform fits, etc..

The inversion process is for sure to some extent non unique, since the results are affected both by the choice of the (usually oversimplified or sometimes even not appropriate) velocity model and of the inversion parameters. E.g., , with respect to the latter only, a specific station selection covering different azimuthal and distance ranges, different frequency bands analyzed, the fitting of body waves only or of full waveforms or the performance of the inversion through either waveform or amplitude spectra fitting, all could contribute to significant differences in the inversion results. If a good quality dataset should ensure a minor deviation between results from different inversion setups, then this requires the reasonable selection of the underlying model and inversion parameters and of the chosen inversion approach. These should be tuned as good as possible to the event size, its depth, the reliability of the available velocity model, the seismic instrumentation, data acquisition and processing, and the source-stations geometry.

Here, we describe how to use the *rapidinv* python code to perform the inversion. *rapidinv* allows the user to customize the inversion procedure, within certain limits, and make use of the Kiwi tools inversion modules without directly dealing with these tools. *rapidinv* acts as a user friendly interface to these tools. Its potential may be further exploited by advanced users. In particular, *rapidinv* internally calls several times the Kiwi tool *minimizer*, which is used to assess source model parameters, generate synthetic seismograms, filter and taper synthetics and observed seismograms, compare them and compute misfits, perform grid search or Levenberg-Marquardt inversion for selected source parameters, and export seismograms in different formats.

*rapidinv* always performs the inversion in 3 separate steps, as described in Cesca et al. (2010) (DC and finite source inversion), and Cesca et al. (2013) (DC and full MT inversion). The first and second steps have to be carried out to obtain a point source solution, the third step is only required to perform an additional finite, kinematic source inversion.

The first step is typically performed as an amplitude spectra inversion. The pure DC results include strike, dip, rake (4 configurations because of the polarity ambiguity of the focal mechanism), centroid depth, scalar moment and magnitude. The full moment tensor (MT)

results additionally include moment tensor components (2 configurations because of the polarity ambiguity) and moment tensor decomposition (see also IS 3.9 and EX 3.5).

The second inversion step is always performed in the time domain, to resolve the polarity ambiguity and to search for the preferred centroid locations. Previous results are improved through the solution of the polarity ambiguity. Additionally, the relative epicentral location and time of the centroid are found. Location and times are defined with respect to the hypocentral location (in terms of spatial shift along North/South and East/West) and nucleation time (in terms of relative time). Both these reference parameters are defined by the user prior to the inversion, and are typically based upon a specific source location result or seismic catalogue information.

After completion of the first and the second inversion step we leave the framework of point source inversion and try to invert for kinematic parameters of the extended source. The background for doing so and the source models used to keep the inversion problem feasible is given in Heimann (2011) and Cesca et al.(2010). The third inversion step for kinematic parameters of the extended source is preferably performed in the frequency domain, including higher frequencies, which should help to estimate finite source parameters. Among the possible resolved parameters are: the preferred rupture plane orientation (discrimination between rupture and auxiliary plane), rupture directivity, rupture velocity, size and duration.

The inversion is preferably performed in the WORK directory, where all local python (<http://www.python.org>) codes (rapidinv, Cesca et al. 2010; mopad, Krieger & Heimann 2013) are locally stored.

The following command gives a list of the initial directory content:

```
ls WORK/*
```

\*.py and \*.pyc are locally stored python scripts. rapidinv\* (\* denotes different version which may be available at different stages) is the script to perform the source inversion. mopad is a tool to perform moment tensor decomposition and plotting (see Krieger and Heimann 2013), which is internally used for these purposes.

*rapidinv.inp.\** are example of input files, for different events or inversion setups;  
*rapidinv.defaults* includes the default setup of inversion variables;  
*rapidinv.acceptables* is a control file to verify very roughly the inversion variables choice.

## 5 Selection of inversion parameters

The inversion is customized after building an own input file. To have an idea, how such an input file looks like, we can open with an editor the file *rapidinv.inp.synth1*. It can be seen that the file includes a list of variables (first column) and a list of values (second column). The most important variables are described in the following. A complete list of variable definition and accepted values is given in the rapidinv manual in the VirtualBox in the directory DOCS.

The input file should be kept as short as possible, and only contains those variables which are specific for the specific event inversion. All other variables, those kept to the defaults values and those common for all studied events, should be stored in the file *rapidinv.defaults*.

### 5.1 Important global variables:

DATA\_DIR: Path to the directory containing all data and station information.

DATA\_FORMAT: Expected format of input displacement data (see kinherd.org for more details).

STAT\_INP\_FILE: (Default: stations.dat): Name of the input file with list of stations to be used. This file, with the proper format, should exist and be saved in the data directory (see DATA\_DIR). Specific file format (manual). All stations herein indicated will be considered. If data are missing, the station will be excluded. If data are partially missing, only existing components will be used. If data files exist, but the station name is not included in the list, data will not be used.

INVERSION\_DIR: Path to the directory where all output files will be saved.

NUM\_INV\_STEPS: Number of inversion steps to be realized (1 = only focal mechanism, 2 = focal mechanism and centroid location, 3 = full point and kinematic inversion).

COMP\_2\_USE: The string should include one letter for each spatial component to consider. Letters follow the convention from kinherd.org (d: down; u: up; n: North; s: South; e: East; w: West; r: transversal, rightward as seen from source to receiver; l: transversal, leftward as seen from source to receiver; a: radial, away from source; c: radial, backward to source).

EPIC\_DIST\_MIN, EPIC\_DIST\_MAX: Minimum and maximum epicentral distance to be considered for all steps.

LATITUDE\_NORTH, LONGITUDE\_EAST: Original latitude and longitude (deg) of the epicenter. Further relocation will be relative to this value.

SW\_FILTERNOISY: Switch to detect and remove noisy traces.

SW\_WEIGHT\_DIST: Apply a distance-dependent weight, w:  $w = \text{station\_epicentral\_distance} / \text{maximal\_epic\_distance}$ .

SW\_FULLMT: Switch to additionally run full moment tensor inversion

### 5.2 Important variables for inversion step 1:

BP\_F1\_STEP1, BP\_F2\_STEP1, BP\_F3\_STEP1, BP\_F4\_STEP1: Bandpass frequency (e.g. 0.009 0.01 0.1 0.11) at inversion step 1.

DEPTH\_BOTTOMLIM, DEPTH\_UPPERLIM: Minimum and maximum accepted depth (km) after inv. step 1 (all other solutions will be removed)

DEPTH\_1, DEPTH\_2, DEPTH\_STEP; SCAL\_MOM\_1, SCAL\_MOM\_2, SCAL\_MOM\_STEP; STRIKE\_1, STRIKE\_2, STRIKE\_STEP; DIP\_1, DIP\_2, DIP\_STEP; RAKE\_1, RAKE\_2, RAKE\_STEP: Min, Max, Increment of depth (km), moment (Nm) and fault angles (deg) to define starting configurations, during inversion step 1.

SW\_RAPIDSTEP1: If set TRUE will ignore STRIKE\_1, STRIKE\_2, ... and test 10 default configurations of strike-dip-rake.

INV\_MODE\_STEP1: Defines the strategy to carry out inversion step 1. The following possibilities are allowed (e.g. invert\_dmsdst: gradient inversion of invert strike, dip, rake, moment, depth)

MISFIT\_MET\_STEP1: Defines the misfit definition for inversion step 1 (ampspec\_l1norm: amplitude spectra will be compared, using L1 norm; ampspec\_l2norm: amplitude spectra will be compared, using L2 norm; l1norm: time traces will be compared, using L1 norm; l2norm: time traces will be compared, using L2 norm).

PHASES\_TO\_USE\_ST1: Seismic phases to be used for inv. Step 1 (p: P phases on all used components, as defined in COMP\_2\_USE; b: Bodywaves, P on vertical component, S on remaining components; a: Full waveform on all used components, as defined in COMP\_2\_USE).

WEIGHT\_A\_ST1, WEIGHT\_P\_ST1, ...: Defines a weight for the time window for phase a (p, ...) during inversion step 1. It is used only if the phase is activated in PHASES\_TO\_USE\_ST1.

WIN\_LENGTH\_A\_ST1, WIN\_LENGTH\_P\_ST1, ...: Defines the length (s) of the time window for phase a (p, ...) during inversion step 1.

WIN\_START\_A\_ST1, WIN\_START\_P\_ST1, ...: Defines the starting time of the time window for phase a (p, ...) during inversion step 1. The value indicates the position of theoretical first P (or S) phase within the time window, defined as percentage of the window length (e.g. 0.02 for a window length of 100s, indicates that the window will start to have the theoretical first P phase arrival time at 2% of the window length).

WIN\_TAPER\_A\_ST1, WIN\_TAPER\_P\_ST1, ...: Defines the tapering of the time window for phase a (p, ...) during inversion step 1. A taper is applied in the time domain, smoothing the time window at both sides. The length of the smoothed part of each side is defined by the given real value, which is defined as a percentage of the time window length.

### 5.3 Plotting variables for inversion step 1:

DATA\_PLOT\_STEP1: Define if data format for plotting result after inversion step 1 is amplitude spectra or displacements). Acceptable values are amsp or seis.

AMPL\_PLOT\_STEP1: Amplitudes of plotted spectra/waveforms (amax: amplitudes of different traces have the same scale; norm: amplitudes are normalized, they are enlarged to the maximal possible scale).

FILT\_PLOT\_STEP1 Defines the format (plain = unfiltered, filtered, tapered) of time series for plotting results after inversion step 1.

START\_PLOT\_STEP1, LEN\_PLOT\_STEP1, TICK\_PLOT\_STEP1: Defines the start, length and tick interval (s) of time series for plotting results after inversion step 1. These are used only if DATA\_PLOT\_STEP1 is seis.

#### 5.4 Important (and plotting) variables for inversion step 2:

EPIC\_DIST\_MAXLOC: Additional constraint on maximum epicentral distance to consider for inversion step 2 (where maximum distance will be the minimum between EPIC\_DIST\_MAX and EPIC\_DIST\_MAXLOC).

GFDB\_STEP2: GFDB used to calculate synthetic seismogram during inversion step 2.

MISFIT\_MET\_STEP2: Defines the misfit definition for inversion step 1 (l1norm: time traces will be compared, using L1 norm; l2norm: time traces will be compared, using L2 norm)

REL\_EAST\_1, REL\_EAST\_2, REL\_EAST\_STEP; REL\_NORTH\_1, REL\_NORTH\_2, REL\_NORTH\_STEP: Min, max and increment of relative location along East and North direction (meters) to define the group of starting configuration, during inversion step 2.

REL\_TIME1, REL\_TIME\_2, REL\_TIME\_STEP: Min, max and increment of relative time offset (seconds) to define the group of starting configuration, during inversion step 2.

PHASES\_TO\_USE\_ST2; WEIGHT\_\*\_ST2, WIN\_LENGTH\_\*\_ST2, WIN\_START\_\*\_ST2, WIN\_TAPER\_\*\_ST2: Analogous to the case as for inversion step 1.

BP\_F1\_STEP2, BP\_F2\_STEP2, BP\_F3\_STEP2, BP\_F4\_STEP2: Bandpass inversion step 2.

DATA\_PLOT\_STEP2: Define if data format (amsp, seis) for plotting result after inversion step 2 (amplitude spectra/displacements)

#### 5.5 Important (and plotting) variables for inversion step 3:

EPIC\_DIST\_MAXKIN: Additional constraint on maximum epicentral distance to consider for inversion step 3 (where maximum distance will be the minimum between EPIC\_DIST\_MAX and EPIC\_DIST\_MAXKIN).

GFDB\_STEP3: Defines the GFDB used to calculate synthetic seismogram during the inversion step 3.

MISFIT\_MET\_STEP3: Defines the misfit definition for inversion step 3 (ampspec\_l1norm: amplitude spectra will be compared, using L1 norm; ampspec\_l2norm: amplitude spectra will be compared, using L2 norm; l1norm: time traces will be compared, using L1 norm; l2norm: time traces will be compared, using L2 norm).

REL RUPT\_VEL\_1, REL RUPT\_VEL\_2, REL RUPT\_VEL\_S: Min, max, increment of relative rupture velocity for starting configurations of inv. Step 3.

PHASES\_TO\_USE\_ST3; WEIGHT\_\*\_ST3, WIN\_LENGTH\_\*\_ST3, WIN\_START\_\*\_ST3, WIN\_TAPER\_\*\_ST3: Analogous as for inversion step 1 (use of bodywaves may work better for location)

BP\_F1\_STEP3, BP\_F2\_STEP3, BP\_F3\_STEP3, BP\_F4\_STEP3: Bandpass inversion step 3.

DATA\_PLOT\_STEP3: Define if data format (amsp, seis) for plotting result after inversion step 2 (amplitude spectra/displacements)

SW\_APPDURATION: Activate fast directivity inversion (uses BP and taper from inversion step 3)

Once all parameters are modified we are ready to perform the inversion

## 6 Moment tensor inversion step by step

The inversion procedure is here described for the case of the SYNTH1 event, according to the original rapidinv.inp.synth1 inversion setup.

Go to the working directory and open the chosen input file.

Check DATA\_DIR points to the correct data directory

Check GFDB\_STEP1, GFDB\_STEP2, GFDB\_STEP3 point to the correct database

Adapt inversion parameters to user wishes.

Check that specific relevant parameters are fixed, in particular those defining the source parameters which are considered to be known, when starting the moment tensor inversion, This include the event origin time, its hypocentral location, and a first moment estimate. Both depth and moment will be . This information is typically available from global catalogue, such as NEIC or GCMT for earthquakes above Mw 5.5, or from local agencies in the case of smaller magnitude events of regional interest. These parameters are provided for all test datasets. For synthetic dataset, the true source parameters are given, while for real dataset, source parameters were chosen according to the information provided either by NEIC, GCMT or EMSC-CSEM.

Known source parameters for the event SYNTH1 are as follows:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2012-03-15 15:00:00 |
| Lat N                  | 47.6667             |
| Lon E                  | 12.0167             |
| Depth (rough)          | 15km                |
| Mw (rough)             | 6.0                 |
| M <sub>0</sub> (rough) | 1e18Nm              |

We are now ready to run the inversion. This is done by typing in the working directory:

```
python rapidinv12.py rapidinv.inp.synth1
```

The code first read rapidinv.defaults and assign default values to all variables.

Then it reads the input file and overwrites all selected variables (repeated variable assignment imply the last assignment will overwrite previous ones)

Finally, a rough control on variable values is performed using the file rapidinv.acceptables

Then, the following tasks are performed:

- Create/overwrite results directory;
- Filter stations according to selected epicentral distance ranges;
- A number of starting source configuration for the DC inversion is built, according to input parameters, and the DC inversion is then performed.
- The best DC solution, together with a number of non-DC solutions, constitute the starting source configurations for the full MT inversion, and the MT inversion is then performed.
- The first inversion step is successfully completed when two GMT scripts are created, executed and two postscript files generated: step1.ptsolution.ps and step1.mtsolution.ps

*step1.ptsolution.ps* (see Figure 1, obtained for event SYNTH1) shows the results of the pure DC inversion after inversion step 1. Source parameters, including location, depth, moment, magnitude, strike-dip-rake configurations and misfit are given in the top left section of the figure. The top right section is dedicated to the relative misfit variations with respect to the best solution, when perturbing single source parameters (depth, strike, dip, rake). These curves are expected to have a minimum in correspondence of the preferred solution, the variability of the minima broadness provides information on the relative resolution of different source parameters (e.g. strike vs. dip vs. rake).

The bottom panel of *step1.ptsolution.ps* is dedicated to waveform or spectra comparison (red colors are used for data, black for synthetics). Waveform plots additionally show a gray area denoting the applied time domain taper. Stations are sorted on the base of epicentral distances, with station name, distance, azimuth and maximal amplitudes provided on the left side.

**Figure 1** *step1.ptsolution.ps*

*step1.mtsolution.ps* (figure 2, obtained for event SYNTH1) provides a similar representation for the full MT inversion results (for the definition of the full MT parameter set (centroid location and time, CLVD, isotropic components etc. see IS 3.9):

**Figure 2** *step1.mtsolution.ps*

The second inversion step is carried out in the time domain, by comparing observed and synthetic displacement waveforms, for a reduced set of focal mechanisms, decided upon results of inversion step 1. The inversion step 2 for DC solution is performed as follows:

- Two possible DC focal mechanisms, with opposite polarities are used to build synthetics. After waveform cross-correlation, waveforms fits are evaluated and the polarity chosen.
- A grid search for the centroid location and centroid time (as relative location and time

with respect to the original epicentral location and origin time respectively) is performed, and best centroid location/time found.

- Polarities are also tested for the best location also for the best full MT solution, and the polarity chosen. A full MT decomposition, through DC, compensated linear vector dipole (CLVD) and isotropic components is then performed.
- The second inversion step is successfully completed when two GMT scripts are created, executed and two postscript files generated: *step2.ptsolution.ps* (figure 3) and *step2.mtsolution.ps*

**Figure 3** *step2.ptsolution.ps*

*step2.ptsolution.ps* shows the results of the pure DC inversion after inversion step 2. Improved source parameters are given in the top left section of the figure. The top right section is dedicated to the relative misfit variations for the centroid location and centroid time

grid search (reference location is at 0, 0; reference time at 0). Larger circle sizes correspond to lower misfits. Red circles denote best solutions. The bottom panel is again dedicated to waveform (or spectra) comparison (red colors are used for data, black for synthetics). Waveform plots additionally show a gray area denoting the applied time domain taper. Stations are sorted on the base of epicentral distances, with station name, distance, azimuth and maximal amplitudes provided on the left side.

The moment tensor polarity is similarly obtained, by comparing waveform fits for both full MT solution with opposite polarity. The resulting plot (step2.mtsolution.ps, shown in figure 4 for event SYNTH1) illustrates the result of moment tensor decomposition, according to DC, compensated linear vector dipole (CLVD) and isotropic (ISO) components.

**Figure 4** *step2.mtsolution.ps*

Prior to the complete finite source inversion, a quick directivity inversion is carried out (see Cesca et al. 2011 for details), by inverting the apparent source duration at single stations, and plot its dependance on the station azimuth. Results can be seen in the file *apparentdurations.ps*. This file shows the results of the quick directivity detection analysis. The map on the right side of the plot illustrate the study region, the epicenter (star), and the station locations (circles). Circle colors denote the apparent duration seen at that station, according to the color bar. The azimuthal distribution of the apparent durations are shown on the left graphs, and fitted through a preferred directivity model (more details on expected curve shapes are discussed in Cesca *et al.*, 2011), or through a common, average source time function length (bottom).

Figure 5 shows an example of the file *apparentduration.ps* for event SYNTH8 where rupture directivity towards NNE is correctly resolved.

**Figure 5** *apparentdurations.ps*

- A range of tested found source solutions is built, with two possible fault plane orientations, variable size and directivity (currently hardcoded, and link to the event magnitude), and possibly variable rupture velocity.
- Finally, performs the third inversion step, which is carried out by grid search, evaluating the misfits for all considered finite source solutions. This last step is successfully completed when a GMT script is created, executed and a postscript file generate: *step3.eiksolution.ps*

*step3.eiksolution.ps* (see figure 6, obtained for event SYNTH8) shows the results of the finite source inversion after inversion step 3. Point and finite source parameters (e.g. Fault plane orientation, radius, area, average slip, etc.) are given in the top left section of the figure. The top right section is dedicated to the rupture propagation (color denote times of excitation,

lines correspond to rupture isochrones) along the rupture plane (x axis: along strike; y axis: along dip) and relative misfit variations for solutions of different radius and relative rupture velocity).

The bottom panel is again dedicated to waveform (or spectra) comparison (red colors are used for data, black for synthetics). Waveform plots additionally show a gray area denoting the applied time domain taper. Stations are sorted on the base of epicentral distances, with station name, distance, azimuth and maximal amplitudes provided on the left side.

Figure 6 *step3.eiksolution.ps*

## 7 Testing cases/exercises

Data, including displacement waveforms and metadata, are provided for 20 earthquakes: 8 of them are synthetic events, the remaining 12 are real earthquakes. Because of the spatial

limitations of the here presented available GFDB all events are shallow (crustal) earthquakes, with an hypocentral depth between 1 and ca. 30km. For the same reason only data for stations at local/regional distances up to a maximum of 1000 km are available. Magnitudes of the events range between Mw 4 and 7.

Real datasets have been selected in order to illustrate possible inversion targets, such as the inversion of pure double couple solutions (moderate magnitude natural earthquakes), full moment tensor solutions (mine collapse induced event), and finite source inversion (larger magnitude earthquakes).

The following events (and directories) are available for the reader to test:

| <i><b>Directory</b></i> | <i><b>Event name</b></i> | <i><b>Dataset short description</b></i>             |
|-------------------------|--------------------------|-----------------------------------------------------|
| SYNTH1                  | Bayrischzell_D           | Synthetic data (DC point source)                    |
| SYNTH2                  | Bayrischzell_D           | Synthetic data (MT point source)                    |
| SYNTH3                  | Bayrischzell_D           | Synthetic data (kinematic bilateral model)          |
| SYNTH4                  | Bayrischzell_D           | Synthetic data (kinematic unilateral model)         |
| SYNTH5                  | Bayrischzell_D           | Synthetic data, wrong model (DC point source)       |
| SYNTH6                  | Bayrischzell_D           | Synthetic data, wrong model (MT point source)       |

Details for each event are provided on the following pages. Together with the event reference name and a short description, the reader should make use of the “Known source parameters”, which are the only needed parameters to build a proper input file for the inversion.

### **SYNTH1**

Event Name: Bayrischzell, Germany Description:

Description:

Synthetic dataset for local inversion. The IASP91 GFDB was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a pure DC point source model.

Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2012-03-15 15:00:00 |
| Lat N                  | 47.6667             |
| Lon E                  | 12.0167             |
| Depth (rough)          | 15km                |
| M <sub>w</sub> (rough) | 6.0                 |
| M <sub>0</sub> (rough) | 1e18Nm              |

Network configuration:

|                   |             |
|-------------------|-------------|
| Stations number   | 10          |
| Station distances | up to 500km |

## **SYNTH2**

Event Name: Bayrischzell, Germany

Description:

The IASP91 GFDB was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a full MT point source model (DC term similar to SYNTH1).

Known source parameters and network configuration: see SYNTH1

## **SYNTH3**

Event Name: Bayrischzell, Germany

Description:

The IASP91 GFDB was used to create synthetic seismograms and no noise is included. Seismograms are obtained for one extended source model (DC similar to SYNTH1).

Known source parameters and network configuration: see SYNTH1

## **SYNTH4**

Event Name: Bayrischzell, Germany

Description:

The IASP91 GFDB was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a different extended source model (DC similar to SYNTH1).

Known source parameters and network configuration: see SYNTH1

## **SYNTH5**

Event Name: Bayrischzell, Germany

Description:

A different crustal model was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a pure DC point source model (same as SYNTH1).

Known source parameters and network configuration: see SYNTH1

## **SYNTH6**

Event Name: Bayrischzell, Germany

Description:

A different crustal model was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a full MT point source model (same as SYNTH2).

Known source parameters and network configuration: see SYNTH1

### **SYNTH7**

Event Name: Bayrischzell, Germany

Description:

A different crustal model was used to create synthetic seismograms and no noise is included. Seismograms are obtained for one extended source model (same as SYNTH3).

Known source parameters and network configuration: see SYNTH1

### **SYNTH8**

Event Name: Bayrischzell, Germany

Description:

The IASP91 dataset was used to create synthetic seismograms and no noise is included. Seismograms are obtained for a different extended source model (same as SYNTH4).

Known source parameters and network configuration: see SYNTH1

### **GER220203A**

Event Name: St. Die, Vosgian\_Mts, France

Description:

Real data (GRSN, MEDNET, GEOSCOPE networks).

Local earthquake with good quality data.

Point source (DC and MT) inversion should be well constrained and easily retrieved.

Kinematic models are not easily resolved, because the rupture model is likely very small for such moderate event.

Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2003-02-22 20:41:01 |
| Lat N                  | 48.33               |
| Lon E                  | 6.67                |
| Depth (rough)          | 12km                |
| Mw (rough)             | 4.5                 |
| M <sub>0</sub> (rough) | 1e16Nm              |

Network configuration:

|                   |             |
|-------------------|-------------|
| Stations number   | 17          |
| Station distances | up to 500km |

### **GER051204A**

Event Name: Waldkirch, Black Forest, Germany

Description:

Real data (GRSN networks).

Local earthquake with good quality data, but poor azimuthal coverage.

Point source (DC and MT) inversion should be well constrained and easily retrieved.

Kinematic models are not easily resolved, because the rupture model is likely very small for such moderate event.

Known source parameters:

|               |                     |
|---------------|---------------------|
| Date/Time     | 2004-12-05 01:52:37 |
| Lat N         | 48.115              |
| Lon E         | 8.077               |
| Depth (rough) | 10km                |
| Mw (rough)    | 4.5                 |

|                        |             |
|------------------------|-------------|
| $M_0$ (rough)          | 1e16Nm      |
| Network configuration: |             |
| Stations number        | 8           |
| Station distances      | up to 500km |

### **GER110996A**

Event Name: Teutschenthal Collapse, Germany

Description:

Real data (GRSN network) from 1996.

Local earthquake with challenging dataset. A complex rupture model is expected, with energy released in different subevents. The collapse of the mine is expected to show relevant implosive components and CLVD.

Point source (DC and MT) inversion should be well constrained and easily retrieved.

Kinematic models are not easily resolved, because the rupture model is very small ( $\leq 1$ km radius).

Known source parameters:

|               |                     |
|---------------|---------------------|
| Date/Time     | 1996-09-11 03:36:35 |
| Lat N         | 51.48               |
| Lon E         | 11.79               |
| Depth         | 1km                 |
| $M_w$ (rough) | 4.5                 |
| $M_0$ (rough) | 1e16Nm              |

Network configuration:

|                   |             |
|-------------------|-------------|
| Stations number   | 10          |
| Station distances | up to 500km |

### **GER201004A**

Event Name: Rotenburg, induced event, Germany

Description:

Real data (GRSN network). Local earthquake.

Point source (DC and MT) inversion should be well constrained and easily retrieved.

Kinematic models are not easily resolved, but perhaps possible, because the rupture velocity was reported as very slow.

Known source parameters:

|               |                     |
|---------------|---------------------|
| Date/Time     | 2004-10-20 06:59:18 |
| Lat N         | 53.01               |
| Lon E         | 9.63                |
| Depth         | 5km                 |
| $M_w$ (rough) | 4.5                 |
| $M_0$ (rough) | 1e16Nm              |

Network configuration:

|                   |             |
|-------------------|-------------|
| Stations number   | 20          |
| Station distances | up to 500km |

### **GRE110406A**

Event Name: Zakynthos\_1, Greece

Description:

Real data (GEOFON, MEDNET, IRIS networks). The earthquake is part of a seismic sequence close to Zakynthos, Greece (other events from the sequence are available).

Regional earthquake.

Point source DC (and MT) and kinematic inversion can be performed.

Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2006-04-11 00:02:40 |
| Lat N                  | 37.64               |
| Lon E                  | 20.75               |
| Depth                  | 20km                |
| M <sub>w</sub> (rough) | 5.5                 |
| M <sub>0</sub> (rough) | 1e17Nm              |

Network configuration:

### **GRE110406B**

Event Name: Zakynthos\_2, Greece

Description:

Real data (GEOFON, MEDNET, IRIS networks). The earthquake is part of a seismic sequence close to Zakynthos, Greece (other events from the sequence are available).  
Regional earthquake.

Point source DC (and MT) and kinematic inversion can be performed.

Known source parameters:

|                        |                     |

### **GRE080608A**

Event Name: Andravida, Greece

Description:

Real data (GEOFON, MEDNET, IRIS networks) with very good quality.  
Magnitude 6.3 earthquake in NW Peloponnese, Greece, with stations at regional distances.  
Point source DC (and MT) and kinematic inversion can be performed.  
Directivity effects can be clearly seen.

Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2008-06-08 12:25:27 |

|-------------------|--------------|
| Stations number   | 20           |
| Station distances | up to 1000km |

**ITA250112A**

Event Name: Emilia, Italy

Description:

Real data from different networks (MEDNET, IRIS, GEOFON, INGV, Univ.Genova).  
The event is relatively weak but the stations distribution unusually dense (inversion may be time consuming if all stations are used).  
Stations are at local distances, most below 200km.  
Point source (DC and MT) inversion should be well constrained and easily retrieved.  
Kinematic models are not easily resolved, because of the small earthquake size/magnitude.

Known source parameters:

|                        |                     |
|------------------------|---------------------|

| Station distances | up to 300km |

**ITA060409A**

Event Name: L'Aquila, Italy

Description:

A well-known earthquake for (Italian) seismologists.  
Real data from different networks (MEDNET, IRIS, GEOFON, GEOSCOPE, GRSN) are available at regional distances.  
Point source (DC and MT) and kinematic inversions can be tested.

Known source parameters:

|           |                     |

| Station distances      | up to 1000km |

### **TUR231011A**

Event Name: Van, Turkey

#### Description:

The largest event in the dataset. This event has recently affected Eastern Turkey, the epicenter close to the city of Van.

Real data from different networks are available at regional distances.

Station distribution is poor and uneven.

Point source (DC and MT) and kinematic inversions can be tested.

#### Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2011-10-23 10:41:22 |

| Stations number   | 5            |
| Station distances | up to 1000km |

### **TUR091111A**

Event Name: Van, Turkey

#### Description:

The strongest aftershock of the 23.10.2011 earthquake (see TUR231011A).

Real data from different networks are available at regional distances.

Station distribution is poor and uneven. The azimuthal gap is very large.

Point source (DC and MT) and kinematic inversions can be tested.

#### Known source parameters:

|                        |                     |
|------------------------|---------------------|
| Date/Time              | 2011-11-09 19:23:35 |
| Lat N                  | 38.35               |
| Lon E                  | 43.40               |

|-------------------|--------------|
| Stations number   | 6            |
| Station distances | up to 1000km |

## **Acknowledgment**

The facilities of GEOFON and IRIS Data Management System, and specifically the IRIS Data Management Center, were used to access part of the waveform and metadata required in this study. Part of data and metadata relative to earthquakes in Germany and surrounding areas were provided by BGR in Germany. We acknowledge all institutions providing seismic

data used in this research. Figures have been prepared with GMT (Wessel and Smith 1998) and MoPaD (Krieger and Heimann 2013).

## 1 Introduction

In seismology the problem of understanding and describing the seismic source consists in relating observed seismic waves (i.e., seismograms) generated by this source to suitably conceived geometric, kinematic and dynamic parameters of a mechanical source model that represents the physical phenomenon of a brittle fracture in the Earth's lithosphere. Representations of the source are defined by parameters whose number depends on the complexity of the source models (e.g., Aki and Richards, 1980 and 2002; Ben-Menahem and Singh, 1981; Das and Kostrov, 1988; Lay and Wallace, 1995; Udías, 1999 and 2002). In the direct problem, theoretical seismic wave displacements are determined from source models and in the inverse problem parameters of source models are derived from observed wave displacements. In the following we will consider only source models related to earthquakes and explosions (see Chapter 3), volcanic tremors (see Chapter 13) and rock bursts. Here we will not discuss sources of seismic noise (see Chapter 4).

Strong non-linear and non-elastic processes take place in a seismic source volume. Parts of it may crack, phase transitions may take place, the temperature may increase, and so on. These kinds of processes are not described by most seismic source theories; however, there are special theories to model such processes, e.g., the time-dependent pressure within an explosion cavity, the rupture propagation on an earthquake fault, and the material behavior on a crack tip (crack criteria). We limit ourselves to the phenomenological description of a seismic source. The aforementioned complicated processes need not to be considered when looking only for their integral effect on a surface surrounding the seismic source, i.e., by replacing a volume integral by a surface integral (see, e.g., Aki and Richards, 1980).

## 2 Continuum mechanics

The description of the source mechanism is based on the solution of the equation of motion. In a deformable solid medium this equation is derived from classical Newtonian mechanics. The linearized equation of motion (i.e., by neglecting density changes and other second order effects) is

$$\rho \ddot{u}_i(x_s, t) - \sigma_{ij,j}(x_s, t) = f_i^b(x_s, t) . \quad (1)$$

In this equation  $\rho$  is the density of the solid body,  $u_i$  are the components ( $i = 1, 2, 3$ ) of the displacement field that describe the deformation of the body,  $\sigma_{ik}$  is the stress tensor,  $f_i^b$  is the body force density acting per unit volume,  $\ddot{u}_i$  is the second time derivative  $\partial^2/\partial t^2$  of the displacement and the comma between two subscripts, e.g., in  $\sigma_{ik,k}$  indicates the spatial derivative of the considered quantity. We generally use the *summation convention* which requires that one has to sum when a subscript appears twice, e.g.,

$$\sigma_{ik,k} = \frac{\partial}{\partial x_1} \sigma_{i1} + \frac{\partial}{\partial x_2} \sigma_{i2} + \frac{\partial}{\partial x_3} \sigma_{i3} .$$

The displacement is a function of the spatial co-ordinates  $x_i$  and the infinitesimal deformation is defined as

$$du_i = u_{i,k} dx_k \quad (2)$$

with

$$u_{i,k} = \beta_{ik} \quad (3)$$

as the distortion tensor. We now consider the location of a particle before and after it is deformed, described by the vectors  $a_i$  and  $x_i$ , respectively. Accordingly, an infinitesimal vector  $da_i$  at the point  $a_i$  is moved (i.e., deformed) to the vector  $dx_i$ , as shown in Figure 1.

**Figure 1** Coordinates and vectors describing the displacement field (see text).

Introducing  $ds^2$ , which is the difference between the square of the length of the vectors  $dx_i$  and  $da_i$ , and, thus, a measure of the deformation of the body, i.e.,  $ds^2 = dx_i dx_i - (dx_i - du_i)(dx_i - du_i)$ , we get with (2) and (3)

$$ds^2 = (\beta_{ij} + \beta_{ji} - \beta_{ki} \beta_{kj}) dx_i dx_j = 2\varepsilon_{ij} dx_i dx_j. \quad (4)$$

Equation (4) is the definition of the *strain tensor*  $\varepsilon_{ij}$ . It is a symmetric tensor. For small deformations it can be approximated by its linear terms

$$\varepsilon_{ij} = \frac{1}{2} (\beta_{ij} + \beta_{ji}) = \frac{1}{2} (u_{i,j} + u_{j,i}). \quad (5)$$

Thus, the strain tensor  $\varepsilon_{ij}$  is the symmetric part of  $\beta_{ij}$ . Any symmetric tensor can be transformed into a co-ordinate system such that

$$\varepsilon_{ij} = \varepsilon^{(i)} \delta_{ij} \quad (6)$$

where  $\delta_{ij}$  is the dimensionless *Kronecker symbol*, defined by

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases} \quad (7)$$

and  $\varepsilon^{(i)}$  are the eigenvalues of the strain tensor. The co-ordinate system where  $\varepsilon_{ij}$  is of the form (6) is called system of principle axes. The three eigenvalues describe the relative deformation in direction of the principle axes.

In continuum mechanics one distinguishes between body forces and surface forces. The body forces are sometimes also termed volume forces because they act on volume elements  $dV$  of the body. In Equation (1) we consider infinitesimal masses  $\rho dV$  where  $dV$  is the infinitesimal volume of the mass element. Accordingly, an infinitesimal body force (Aki and Richards, 1980) can be written as  $dF_i = f_i^b(x_s, t) dV$ . Typical examples of body forces are the gravity field and the centrifugal force.

In contrast, surface forces such as cohesion, the sliding friction, or the internal stress during the deformation of the body, act on surface elements  $dS$  of the volume  $dV$ . The stress is a tensor of second order, i.e., it has two subscripts, because it is characterized both by the orientation of the force and by the orientation of the surface on which the force acts. A second-order tensor has generally 9 independent components which can be written explicitly as

$$\sigma_{ij} = \begin{pmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{pmatrix}.$$

In general,  $\sigma_{ij}$  depends on position and time. It acts only between adjacent particles. Because of the conservation law of angular momentum this tensor has to be symmetric, i.e.,

$$\sigma_{ij} = \sigma_{ji}. \quad (8)$$

The relation between the incremental body force density  $df_i^s$  which acts on an internal surface element  $dS$  and the stress is

$$df_i^s = \sigma_{ij} n_j dS \quad (9)$$

where  $n_j$  is the normal vector of the surface elements (see Figure 2).  $\sigma_{ij} n_j$  is called the *traction* of the stress tensor. The pressure and the surface tension in fluids are special examples of internal surface forces. Figure 3 shows the different components of  $\sigma_{ij}$  which act on the surfaces of an infinitesimal cube.

In the linear theory of elasticity, the strain and the stress tensor are linearly coupled. A relatively simple stress-strain relation is the generalized *Hook's law*

$$\sigma_{ij} = c_{ijkl} \varepsilon_{kl}. \quad (10)$$

**Figure 2** Schematic depiction of the considered source volume  $dV$ , a surface element  $dS$  (with its normal vector  $n_i$ ) on which the force  $df_j^s$  acts.

**Figure 3** The nine components of the stress tensor.  $\sigma_{ij}$  are the components of the stress tensor parallel to  $x_j$  on planes having  $n_i$  as their normals.

The body that obeys the relation (10) is said to be *linearly elastic*. The  $c_{ijkl}$  are called *elastic constants* because they are independent of strain, however, in the case of an inhomogeneous medium, they depend on the position in the body. Due to the symmetry of strain (see Equation (5)) and stress tensor (see Equation (8)) and because of the energy balance in the body, the fourth-order tensor  $c_{ijkl}$  has the following three symmetries:

$$c_{ijkl} = c_{jikl}, \quad c_{ijkl} = c_{ijlk}, \quad \text{and} \quad c_{ijkl} = c_{klij}. \quad (11)$$

These symmetries reduce the independent components in  $c_{ijkl}$  from 81 to 21. In the case of an *isotropic medium*, i.e., when the elastic properties are independent of the orientation in the body, the elastic constants reduce to just two. Then  $c_{ijkl}$  has the form

$$c_{ijkl} = \lambda \delta_{ij} \delta_{kl} + \mu (\delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}). \quad (12)$$

The two parameter  $\lambda$  and  $\mu$  are known as the *Lamé constants*.

If attenuation has to be included the relatively general *Boltzmann law*

$$\sigma_{ij}(t) = \int_{-\infty}^t b_{ijkl}(t - \tau) \varepsilon_{kl}(\tau) d\tau \quad (13)$$

can be used.

It is advantageous to introduce now the *Fourier transform*  $f(\omega)$  of a time dependent function  $f(t)$ . Here,  $\omega$  is the angular frequency  $2\pi f$ , where  $f$  is frequency in units of Hz.. We use the definitions

$$f(\omega) = \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad \text{and} \quad f(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(\omega) e^{i\omega t} d\omega \quad (14)$$

where  $i = \sqrt{-1}$  is the imaginary unit, and  $f(\omega)$  is a complex function, called the complex spectrum of  $f(t)$ . It can be represented by

$$f(\omega) = a(\omega) + i b(\omega) = A(\omega) e^{i\Phi(\omega)}$$

where  $A(\omega)$  is the amplitude spectrum and  $\Phi(\omega)$  the phase spectrum.  $a(\omega)$  and  $b(\omega)$  are the real and the imaginary parts of  $f(\omega)$ , respectively. When applying the Fourier transformation to Equation (13) the integral is replaced by the product of  $b_{ijkl}(\omega)$  and  $\varepsilon_{kl}(\omega)$ . The imaginary part of  $b_{ijkl}$  describes a linear attenuation for a propagating displacement field.

With Eqs. (5), (10), and (14) the equation of motion (1) becomes (Udías, 1999)

$$\rho \omega^2 u_i(x_s, \omega) + \sigma_{ij,j}(x_s, \omega) = -f_i^b(x_s, \omega) \quad (15)$$

and in a linear elastic but inhomogeneous medium

$$\rho \omega^2 u_i(x_s, \omega) + (c_{ijkl} u_{k,l}(x_s, \omega))_{,j} = -f_i^b(x_s, \omega). \quad (16)$$

The second term on the left side is the stress due to the displacement  $u_k$ . In order to specify  $u_i$  in a unique way, the initial conditions have to be fixed for the displacement  $u_i$  and the related velocity  $\dot{u}_i$  as well as the boundary conditions for the displacement or the traction. The homogeneous initial condition, that both  $u_i$  and  $\dot{u}_i$  are zero before the beginning of the seismic event, is the precondition for the existence of the related Fourier transform  $u_i(x_s, \omega)$ . Boundary conditions can be specified for the displacement  $u_i$  or the traction  $\sigma_{ij} n_j$  on internal surfaces  $S$  (or *external surfaces* such as the Earth's free surface) (see Figure 4), namely

$$u_i(\xi_s, \omega) \quad \text{or} \quad \sigma_{ij}(\xi_s, \omega) n_j \quad \text{on the internal surface } S(\xi_s) \quad (17)$$

where  $S(\xi_s)$  may consist of several unconnected surfaces. The Greek letter  $\xi_s$  used as coordinates should indicate that the quantities  $u_i$  and  $\sigma_{ij}$  are lying on the surface  $S(\xi_s)$  which is generally curved. These boundary conditions are indispensable for modeling seismic sources and computing the wave propagation through a layered medium.

**Figure 4** Illustrating the definition of boundary conditions for seismic faults representation.

### 3 Kinematic source models

The first mathematical formulation of the mechanism of earthquakes used the representation of the processes at the source by a distribution of the body force density  $f_i^b(\xi_s, t)$  acting inside the source volume  $V_0$ . Since these forces must represent the phenomenon of fracture, they are called equivalent forces. If it is assumed that no other body forces are present (gravity, etc.), and that on its surface  $S$  displacements and tractions are zero, we can use the representation theorem in terms of the *Green's function* to write the elastic displacements in an infinite medium in the time domain as

$$u_i(x_s, t) = \int_{-\infty}^{\infty} d\tau \int_{V_0} f_k^b(\xi_s, t) G_{ik}(x_s, t, \xi_s, \tau) dV \quad (18)$$

or in the frequency domain by

$$u_i(x_s, \omega) = \int_{V_0} f_k^b(\xi_s, \omega) G_{ik}(x_s, \xi_s, \omega) dV. \quad (19)$$

The Green's function  $G_{ki}$  is the solution of the equation of motion (16) for special impulsive single point forces, termed *Dirac* or *needle impulses*, which act inside the body. The spectrum of the Dirac impulse is 1 for all frequencies and, thus, does not appear in Equation (20) below. According to Ben-Menahem and Singh (1981) and Udías (1999), the following equation holds for the Green's function

$$\rho \omega^2 G_{in}(x_r, \xi_r, \omega) + (c_{ijkl} G_{kn,l}(x_r, \xi_r, \omega))_{,j} = -\delta_{in} \delta(x_r - \xi_r) \quad (20)$$

where  $\delta(x_r - \xi_r)$  is the three-dimensional Dirac delta function which is the product of three one-dimensional Dirac delta functions, i.e.,  $\delta(x_r - \xi_r) = \delta(x_1 - \xi_1) \delta(x_2 - \xi_2) \delta(x_3 - \xi_3)$ . Note that  $\delta(x_r - \xi_r)$  has the dimension of 1/(unit volume). The three one-dimensional Dirac functions define the point in space where the three perpendicular point forces, as described by the Kronecker symbol in Equation (7), act.

The Green's function acts as a "propagator" of the effects of forces  $f_i^b$ , from the points where they are acting ( $\xi_i$  inside  $V_0$ ) to points  $x_i$  outside  $V_0$ , where the elastic displacement  $u_i$  produces the seismogram. A simplification, often used in the practice, is made by applying the point source approximation. It is valid if the source dimension is much smaller than the considered wavelength and the distance of the observation point from the source. For a point source at  $x_s^0$  we develop the Green's function in Equation(19) in a Taylor series at this point:

$$\begin{aligned} u_i(x_s, \omega) &= \int_{V_0} \left[ f_k^b(x_s^0 + s_s, \omega) G_{ik}(x_s, x_s^0, \omega) + s_j f_k^b(x_s^0 + s_s, \omega) \frac{\partial}{\partial x_j^0} G_{ik}(x_s, x_s^0, \omega) + \dots \right] dV(s_s) \\ &= F_k(x_s^0, \omega) G_{ik}(x_s, x_s^0, \omega) + M_{jk}^f(x_s^0, \omega) G_{ik,j}(x_s, x_s^0, \omega) + \dots \end{aligned} \quad (21)$$

If the source volume is small the Taylor series can be finished after the second term with the first derivative to the source co-ordinates  $x_i^0$ . Then (21) defines the force  $F_k$  and a seismic moment tensor  $M_{kl}^f$  for which the following relations hold:

$$F_k(x_s^0, \omega) = \int_{V_0} f_k^b(x_s^0 + s_s, \omega) dV(s_s) \quad (22)$$

and

$$M_{jk}^f(x_s^0, \omega) = \int_{V_0} s_j f_k^b(x_s^0 + s_s, \omega) dV(s_s). \quad (23)$$

If  $f_k^b$  is a single point force then  $M_{kl}^f$  as a whole describes a force couple (see Figure 5).

**Figure 5** Schematic presentation of a general force couple  $f_i s_j$

Equation (21) contains the partial spatial derivatives of the Green's function. In a homogeneous infinite body they can be written as

$$G_{ki,j} = \frac{1}{r^4 \omega^2} \sum_{n=0}^3 A_{ijk}^{(n)P} \left( \frac{\omega r}{v_p} \right)^n + \frac{1}{r^4 \omega^2} \sum_{n=0}^3 A_{ijk}^{(n)S} \left( \frac{\omega r}{v_s} \right)^n \quad (24)$$

where the  $A_{ijk}^{(n)}$  are complex coefficients proportional to the amplitudes and phases of the P and S waves (see 2.2). The term of  $G_{ij,k}$  with  $n = 3$  is called the *far-field term* because it can still be observed at rather large distances  $r$  between the point source and the point of observation (seismic recording). In contrast, the terms with  $n = 0, 1$  and  $2$  are called the *near field terms* because they decay with distance more rapidly than the far-field term, namely proportional to  $r^{-2}$ ,  $r^{-3}$ , and  $r^{-4}$ , respectively.

Elastic displacements are given now by the time convolution of the forces acting at the focus with the Green's function for the medium. The simplest Green's function is that corresponding to an homogeneous infinite medium (full space). Internal sources must be in equilibrium, thus satisfying the condition that their resulting total force and moment are zero. Therefore, we consider as a seismic source only the symmetric part of  $M_{kl}^f$  as a seismic moment tensor, i.e.,

$$M_{jk} = M_{jk}^f + M_{kj}^f. \quad (25)$$

Fig. 3.34 shows all possible 6 couples and three dipoles of the seismic moment tensor  $M_{jk}$ .

If we want to represent the shear motion on a fault, the equivalent system of forces is that of two couples with no resulting moment, called a double-couple model (DC) (see Figure 8). If the couples are oriented in the direction of the two perpendicular unit vectors  $e_i$  and  $l_i$ , respectively, with  $e_i l_i = 0$ , and if their scalar seismic moment is  $M_0(\omega) = \lim_{|s_i| \rightarrow 0} |s_i| |F_k|$ , where  $|s_i|$  is the length of the arm of the couple and  $|F_k|$  the amount of the force, the displacement caused by the double-couple source is given by

$$u_i^{DC}(x_s, \omega) = M_0(\omega)(e_k l_j + e_j l_k) G_{ik,j}(x_s, x_s^o, \omega). \quad (26)$$

Note that in the given case the comma in the subscripts of  $G$  represents the partial derivative with respect to the source co-ordinates.

If an earthquake is produced by a fault in the Earth's crust, a mechanical representation of its source can be given in terms of fractures or dislocations in an elastic medium. A displacement dislocation consists of an internal surface  $S$  with two sides ( $S^+$  and  $S^-$ ) inside of the elastic medium (see Figure 5) across which there exists a discontinuity of displacement; however, stress is continuous. Thus,  $S$  is a model of a seismic fault. Coordinates on this surface are  $\xi_k$  and the normal at each point is  $n_i$ . From one side to the other of this surface there is a discontinuity in displacement  $D_i$ , which is termed the slip or dislocation on the fault:

$$D_i(\xi_k, \omega) = u_i^+(\xi_k, \omega) - u_i^-(\xi_k, \omega). \quad (27)$$

The plus and minus signs refer to the displacement at each side of the surface  $S$ . If there are no body forces ( $F_i = 0$ ), and the stresses are continuous through  $S$ , then, for an infinite medium, the equation relating the displacement to the dislocation  $D_i$ , results in

$$u_n(x_s, \omega) = \int_S D_i(\xi_s, \omega) c_{ijkl} n_j(\xi_s) G_{nk,l}(x_s, \xi_s, \omega) dS(\xi_s). \quad (28)$$

Equation (27) corresponds to a kinematic model of the source, that is a model in which elastic displacements  $u_i$  are derived from slip vector  $D_i$ . The latter represents a non-elastic displacement of the two sides of a fault (i.e., of the model surface  $S$ ). In a kinematic model slip is assumed to be known. It is not derived from stress conditions in the focal region as it is in dynamic models. Equation (28) contains the Green's function discussed in conjunction with Equation (24). When seismic waves, generated by the source, are observed in the far-field, i.e., at distances  $r$  much larger than the wavelength and the linear source dimension, then the Green's function is proportional to  $\omega$ . Accordingly, the dominant term of the integrant in Equation (28) is  $\omega D_i$  which is, in the time domain, proportional to the slip velocity. Thus, the elastic displacement observed in the far-field does not depend on the slip in the source but on the slip velocity and, similarly, on the seismic moment rate  $\partial M_{ik}(t)/\partial t = \dot{M}_{ik}$  (see Fig. 2.4). Or, in the frequency domain, the displacement is proportional to  $i\omega M_{kl}(\omega)$ . This means that the source radiates elastic energy only while it is moving; when motion at the source stops it ceases to radiate energy.

The most common model for the source of an earthquake is a shear fracture, that is, a fracture in which the slip  $D_i$  is perpendicular to the normal of the fault. For a fault plane  $S$  of area  $A$  and normal  $n_i$ , the slip  $D_i(\xi_s, t)$  is in the direction of the unit vector  $l_i$  contained in the plane. Accordingly,  $l_i$  and  $n_i$  are perpendicular and the scalar product  $n_i \cdot l_i = 0$ . For an infinite, homogeneous isotropic medium, displacement according to Equation (28) is given by

$$u_i(x_s, \omega) = \int_S \mu |D_l(\xi_s, \omega)| (l_k n_j + l_j n_k) G_{ik,j}(x_s, \xi_s, \omega) dS(\xi_s) \quad (29)$$

For modeling a shear dislocation source, the parameters on the right-hand side of Equation (29) have to be known. Implicitly these parameters include information about the rupture propagation, i.e., on the shape of the crack front, its propagation direction and propagation velocity (crack velocity), and shape of the final ruptured surface  $S$ .

The circular fault and the rectangular fault are the most important approximations. In the first case the rupture begins at the center and the crack front is described by an outward propagating circle. However, the direction of the dislocation is not necessarily radially symmetric. This circular model, described by Brune (1970) and Madariaga (1976), should be valid for small earthquakes with magnitudes smaller than about 4 to 5. Another approximation, for large earthquakes in the Earth's crust in particular, is a rectangular fault model, also called Haskell-model (Haskell, 1964). The length of the fault, generally assumed to be horizontal, is larger than its width (depth) by a factor of 2 to 10 or even more for very large earthquakes. This is due to the limited thickness of the seismogenic zone of the upper lithosphere, usually ranging between about 10 and 25 km, where brittle fracturing is possible. On the other hand, large crustal earthquakes may have a rupture length of 200 km or even more, e.g., about 450 km for the Alaska earthquake of 1964 and about 1000 km for the Chile earthquake of 1960. This rectangular model is also useful for describing deeper earthquakes in subduction zones.

When the Haskell-model is used the behavior of the rupture front must be known. The first approximation is that the rupture starts along a line and propagates unilaterally or bilaterally over the rectangular fault plane (see Figure 6). This approximation is useful for long ruptures with small width (the line-source approximation). It is also suitable for distinguishing between an in-plane and an anti-plane fault geometry. In the case of an in-plane fault the rupture moves into the direction of the slip whereas in the anti-plane case the direction of slip is parallel to the rupture front (see Figure 6).

**Figure 6** Several models of rupture propagation

For describing the rupture propagation in the case of a rectangular fault the following four terms and definitions, shown in Figure 6, are important:

- unilateral rupture propagation – one rupture front propagates over the entire fault plane;
- bilateral rupture propagation – two rupture fronts with different directions propagate over the rupture plane;
- unidirectional rupture propagation – the direction of rupture propagation is parallel to the length of the fault plane; and
- bidirectional rupture propagation – the rupture starts at a point and propagates across the fault plane.

Other models for describing the shape of the fault plane, the shape of the rupture front, and the mode of the rupture propagation are possible.

With respect to the velocity of rupture propagation the most common models assume values between about 0.6 to 0.9 of the shear-wave velocity  $v_s$  (see 2.2) in the source region; however, detailed field and laboratory investigations have shown that both slower (so-called “silent earthquakes”) and supersonic ( $> v_s$ ) rupture propagation velocities are possible (e.g., Tibi et al., 2001). Rupture velocity depends on the material properties, the internal friction of the unbroken material, the frictional conditions along the fractured surface and the stress conditions (ambient and on the crack tip) in the given case.

For the point source approximation Equation (29) takes the simpler form

$$u_i(\omega) = \mu A |D_l(\omega)| (l_k n_j + l_j n_k) G_{ik,j}(\omega) \quad (30)$$

or, in the time domain,

$$u_i(t) = \mu A (l_k n_j + l_j n_k) \int_{-\infty}^{\infty} |D_l(\tau)| G_{ik,j}(t - \tau) d\tau. \quad (31)$$

Displacements are given by temporal convolution of slip with the derivatives of the Green’s function. The geometry of the source is now defined by the orientation of the two unit vectors  $n_i$  and  $l_i$ . These two vectors, which refer to the geophysical co-ordinate system of axes (North, East, Nadir), define the orientation of the source, namely  $n_i$  the orientation of the fault plane and  $l_i$  the direction of slip. These two vectors can be written in terms of the three angles that define the motion on a fault, namely, azimuth  $\phi$ , dip  $\delta$  and rake  $\lambda$ . The shear fracture itself is equivalent to a DC source in terms of forces (see Figure 7).

**Figure 7** Depiction of the equivalence of a shear dislocation with the force double couple and the vector dipole models.

In the case that  $l_i$  and  $n_i$  are not perpendicular, Equation (29) has to be replaced by

$$u_k(x_s, \omega) = \int_S [\lambda \delta_{jk} n_l l_l + \mu (l_k n_j + l_j n_k) G_{ik,j}(x_s, \xi_s, \omega)] D_n(\xi_s, \omega) dS(\xi_s). \quad (32)$$

The special case when  $l_i$  and  $n_i$  are parallel is often used to model tensional volcanic earthquakes (Figure 8).

**Figure 8** Illustration of a tension crack which is often used in modeling volcanic earthquakes.

Another more general representation of seismic source is given by the seismic moment tensor density  $m_{ij}$ . The moment tensor density represents that part of the internal strain drop which is dissipated in non-elastic deformations at the source. So far we have modeled the seismic source by means of the forces in the equation of motion (see Equation (1)) or by boundary conditions for the displacement (see Eqs. (17) and (28)). Now we take another approach and divide the true strain tensor  $\varepsilon_{ij}^{true}$  into an elastic and inelastic part, i.e.,

$$\varepsilon_{ij}^{true} = \varepsilon_{ij}^{ek} - \varepsilon_{ij}^{inel}. \quad (33)$$

With this we define the true stress

$$\sigma_{ij}^{true} = \sigma_{ij} - m_{ij}^V \quad (34)$$

where  $\sigma_{ij}$  is the elastic stress related to the strain by Equation (10) or (13) and  $m_{ij}^V$  is given by

$$m_{ij}^V = c_{ijkl} \varepsilon_{kl}^{inel} . \quad (35)$$

Equation (35) defines the seismic moment tensor density  $m_{ij}^V$ . The superscript  $V$  indicates that it is a volumetric density. Rice (1980) and Madariaga (1983) denote  $\varepsilon_{ij}^{inel}$  as the stress-free strain or transformation strain, and  $m_{ij}^V$  as the stress glut. The seismic moment tensor  $M_{ij}$  is, thus, defined by

$$M_{ij}(\omega) = \int_{V_o} m_{ij}^V(x_k, \omega) dV(x_k) . \quad (36)$$

The quantities  $m_{ij}^V$  and  $M_{ij}$  play a fundamental role in the theory of seismic sources. The relations between the different kinds of stress are shown in Figure 9. When  $\sigma_{ij}$  in (15) is substituted by  $\sigma_{ij}^{true}$  an additional force term appears on the right side. It can be interpreted as an equivalent force density  $f_i^{eq}$  or as an equivalent force  $F_i^{eq}$

$$f_i^{eq}(x_k, \omega) = -m_{ij,j}^V(x_k, \omega) \quad \text{and} \quad F_i^{eq} = -\int_{V_o} m_{ij,j}^V(x_k, \omega) dV(x_k) . \quad (37)$$

**Figure 9** Relationship between the elastic stress  $\sigma_{ij}$ , related to the strain  $\varepsilon$ , the true stress  $\sigma_{ij}^{true}$  and the seismic moment density tensor  $m_{ij}^V$ .

In replacing the body force in Equation (19) by the equivalent force density in Equation (37) an additional volume integral  $-\int_{V_o} G_{ij} m_{jk,k}^V dV$  appear. After an integration by parts and assuming that  $m_{jk}^V$  vanishes on  $S$ , i.e., the inelastic volume is bordered by  $S$ , the displacement produced by  $m_{ij}^V$  is

$$u_i(x_i, \omega) = \int_{V_o} G_{ik,j}(x_s, \xi_s, \omega) m_{jk}^V(\xi_s, \omega) dV(\xi_s) . \quad (38)$$

When comparing Eqs. (38) and (28) one realizes that the integrands have the same form but the integration in (38) is over a volume while it is over a surface in Equation (28).

Accordingly, the stress glut  $m_{ij}^V$  is equivalent to a dislocation when the inelastic volume can be approximated by an inelastic internal surface. Naming this stress glut by  $m_{ij}^S$  from Equation (28) we see that

$$m_{kl}^S = c_{ijkl} D_i n_j \quad (39)$$

for the general linear elastic case and for the shear crack in an isotropic medium holds

$$m_{ij}^S = \mu (D_i n_j + D_j n_i). \quad (40)$$

For the spatially averaged dislocation  $\overline{D_i}(\omega)$ , the seismic moment tensors  $M_{ij}$  in these two cases become

$$M_{ij}(\omega) = c_{ijkl} \overline{D_k}(\omega) n_l A \quad \text{and} \quad M_{ij}(\omega) = \mu [\overline{D_i}(\omega) n_j + \overline{D_j}(\omega) n_i] A, \quad (41)$$

respectively. In the latter case, when  $\overline{D_i}$  and  $n_j$  are perpendicular, the scalar seismic moment is

$$M_0(\omega) = \mu |\overline{D_i}(\omega)| A. \quad (42)$$

In the general case of an arbitrary moment tensor the scalar seismic moment is defined by

$$M_0 = \sqrt{\frac{1}{2} M_{ik} M_{ik}}. \quad (43)$$

## 4 Dynamic source models

Dynamic source models, or crack models, use a given stress on an internal surface (fault) to describe a seismic source. In this case Equation (19) is not valid. In general, two terms must be added to the right side of Equation (19). These terms include boundary conditions for the displacement and the stress. Note that only one of these conditions can be freely chosen while the other one has to be calculated. The computation of the Green's function requires boundary conditions as well, either for the Green's function itself or for the stress produced by it. These boundary conditions do not influence the result of the computation of the displacement  $u_i(x_s, \omega)$ . Therefore, we can freely select any suitable boundary conditions. When selecting a Green's function which produces a vanishing stress on the internal surface  $S$  this Green's function is called  $G_{ij}^{free}$  because the related internal surface behaves like a free surface. The advantage is, that this kind of source representation does not require a knowledge of the displacement produced by the given stress on the internal surface. When no body force acts it holds that

$$u_i(x_i, \omega) = \int_S G_{ik}^{free}(x_s, \xi_s, \omega) n_j \sigma_{kj}(\xi_s, \omega) dS(\xi_s). \quad (44)$$

Equation (44) simplifies the computation of the displacement or the dislocation on the fault when the stress on the fault is given. When using other kinds of representations an inhomogeneous integral equation for  $u_i(\xi_s, \omega)$  on the fault has to be solved.

In the dynamic models the static stress drop  $\Delta\sigma_{ij}$  plays an important role. It is defined as the difference between the stress distribution  $\sigma_{ij}^o$  on the fault plane before the occurrence of the earthquake and the stress  $\sigma_{ij}^1$  after the earthquake. This static stress drop is

$$\Delta\sigma_{ij}(\xi_s) = \sigma_{ij}^o(\xi_s) - \sigma_{ij}^1(\xi_s) \quad (45)$$

with  $\sigma_{ij}^1(\xi_s) = \lim_{t \rightarrow \infty} \sigma_{ij}(\xi_s, t) = \lim_{\omega \rightarrow 0} i\omega \sigma_{ij}(\xi_s, \omega)$ . A more general time dependent stress on the fault is shown in Figure 10 (Yamashita, 1976).

A case of practical importance is that of a circular shear fault. It is probably a good approximation for small earthquakes in the Earth's crust with magnitudes smaller than 4 as long as only frequencies  $< 5$ -10 Hz are considered. If a homogeneous shear stress drop  $\Delta\sigma_{12}$  in the  $x_1$ - $x_2$  plane is assumed, the static dislocation on the fault is

$$D_1 = \frac{8}{\mu\pi} \frac{\lambda + 2\mu}{3\lambda + 4\mu} \Delta\sigma_{12} (R_0^2 - r^2)^{1/2} \quad (46)$$

where  $R_0$  is the final radius of the broken fault and  $r$  the radial co-ordinate. If  $r > R_0$  the dislocation in Equation (46) is zero. By inserting Equation (46) in (41) we get for the static seismic moment

$$M_0 = \frac{16}{3} \frac{\lambda + 2\mu}{3\lambda + 4\mu} \Delta\sigma_{12} R_0^3 \quad (47)$$

and for  $\lambda = \mu$  the well known result derived by Keilis-Borok (1959) is given by

$$M_0 = \frac{16}{7} \Delta\sigma_{12} R_0^3. \quad (48)$$

Similar relations hold for rectangular shear cracks of the length  $L$  and a width  $W$ :

$$M_0 = C L^2 W \Delta\sigma_{12} \quad (49)$$

where  $C$  is a model-dependent constant in the order of 1 and  $\Delta\sigma_{12}$  is uniform over the fault. In the case of a buried in-plane shear crack holds

$$C = \frac{\pi}{8} \frac{\lambda + 2\mu}{\lambda + \mu} \quad (50)$$

and for a buried anti-plane case

$$C = \frac{\pi}{4}. \quad (51)$$

When the fault is perpendicular to the Earth's surface and outcropping then  $C$  in the Eqs. (50) and (51) is twice as large.

**Figure 10** Time dependence of stress at a point on the fault surface during an earthquake.  $\sigma^0$  and  $\sigma^1$  – stress before and after the earthquake,  $\sigma_{fr}$  – fracture strength,  $\bar{\sigma}$  – mean stress,  $\sigma^g$  – friction stress,  $\sigma_{eff}$  – effective stress = dynamical stress drop  $\delta\sigma$  and  $\Delta\sigma$  – static stress drop.

The dynamic relation between the shear stress drop  $\Delta\sigma$  and the dislocation can be calculated numerically. An example is shown in Figure 11. The rupture starts at  $t=0$  and  $r=0$  and expands with constant velocity. The time  $t$  and the dislocation  $|D_I(r,t)|$  are normalized to  $R_0/V_p$  and  $\Delta\sigma R_0/\mu$  where  $V_p$  is the velocity of the P wave ( $V_p^2 = (\lambda + 2\mu)/\rho$  with  $\rho$  as the density of the medium).

**Figure 11** Dislocation function  $D(r, t)$  at several distances from the center on the circular crack plotted against the normalized time  $t$ . For explanation of symbols see text (according to Madariaga, 1976; modified from Aki and Richards, 1980).

## 5 Energy, moment, dislocation and stress drop

The radiated energy of an earthquake can be computed assuming a specific source model and its source parameters. We describe the earthquake as a shear rupture on a surface. In a relatively general form Kostrov (1975) writes for the radiated seismic energy  $E_s$

$$E_s = \int_0^{t_{\max}} dt \int_{S(t)} dS (\xi_k) (\sigma_{ij}^0 - \sigma_{ij}) \dot{D}_i n_j - \frac{1}{2} \int_A dS \Delta \sigma_{ij} D_i^0 n_j - \int_A g dS \quad (52)$$

where  $t_{\max}$  is the maximum duration of the motion on the fault plane,  $S(t)$  the rupture plane developing during the rupture,  $A$  the final rupture plane with  $A = \lim_{t \rightarrow \infty} S(t)$ ,  $\sigma_{ij}^0(\xi_s)$  the stress before the earthquake occurred,  $\sigma_{ij}(\xi, t)$  the stress on the broken fault surface,  $\dot{D}_i(\xi_s, t) = \partial/\partial t D_i(\xi_s, t)$  the dislocation velocity,  $\Delta \sigma_{ij}(\xi)$  the static stress drop (see Figure 10),  $n_j$  the normal vector of the fault surface,  $D_i^0(\xi_s)$  the static dislocation, and  $g$  the specific energy required to generate a new surface. Equivalent to Equation (52) is the often used form

$$E_s = \int_0^{t_{\max}} dt \int_{S(t)} dS \dot{D}_j n_j (\bar{\sigma}_{ij} - \sigma_{ij}) - \int_A g dS \quad (53)$$

where  $\bar{\sigma}_{ij} = (\sigma_{ij}^0 + \sigma_{ij}^1)/2$  denotes the mean stress,  $\sigma_{ij}^0$  is the stress before the earthquake, and  $\sigma_{ij}^1$  is the final stress, which may be equal to the frictional stress. When taking into account the grow of the rupture area during the earthquake in the formulation of the dislocation (source time) function  $D_i(t)$ , Equation (53) becomes

$$E_s = \int_A dS \int_0^{D_i^f} dD_i n_j [\bar{\sigma}_{ij} - \sigma_{ij}(D_k)] - \int_A g dS \quad (54)$$

where  $\sigma_{ij}(D_k)$  is the stress-dislocation relation on the fault plane and  $D_i^f$  the final dislocation.. In the Eqs. (52) to (54) the seismic energy  $E_s$  is composed of released deformation energy  $E_{tot}$ , frictional energy  $E_f$ , and rupture (crack) energy  $E_r$

$$E_s = E_{tot} - E_f - E_r \quad (55)$$

with

$$\begin{aligned} E_{tot} &= \int dS \bar{\sigma}_{ij} D_i n_j \\ E_f &= \int dS \int dD_i n_j \\ E_r &= \int g dS \end{aligned} \quad (56)$$

With this we define the seismic efficiency  $\eta$

$$\eta = \frac{E_s}{E_{tot}}$$

(57)

and the apparent stress  $\sigma_{app}$

$$\sigma_{app} = \frac{1}{A|\overline{D_i}|} \int e dS \quad (58)$$

where  $|\overline{D_i}|$  is the spatial averaged absolute value of the dislocation. The energy density  $e$  is identical with the integrant of the surface integral. Therefore the following relation between the seismic energy and the scalar seismic moment holds:

$$E_s = \sigma_{app} M_0 / \mu \quad (59)$$

Further special cases are:

a)

$\sigma_{ij}^0$ ,  $\sigma_{ij}$ ,  $\sigma_{ij}^1$  are homogeneous and  $\sigma_{ij}$  equal to the time-independent friction stress  $\sigma_{ij}^g$  Eqs. (3), (6) and (7) yield

$$E_s = (\overline{\sigma}_{ij} - \sigma_{ij}^g) D_i^f n_j S_0 - E_r \quad (60)$$

$$\eta = \frac{(\sigma_{ij}^0 + \sigma_{ij}^1 - 2\sigma_{ij}^g) e_i n_j - 2\bar{g}}{(\sigma_i^0 + \sigma_{ij}^1) e_i n_j} \quad (61)$$

$$\sigma_{app} = \frac{1}{2} (\sigma_{ij}^0 + \sigma_{ij}^1 - 2\sigma_{ij}^g) e_i n_j - \frac{\bar{g}}{|\overline{D_i}|} \quad (62)$$

where  $\bar{g}$  is the averaged specific rupture energy and  $e_i$  a unit vector in the direction of the dislocation. With this we get

$$\sigma_{app} = \eta \overline{\sigma}_{ij} e_i n_j. \quad (63)$$

b)

For a shear fracture, and  $\sigma_{ij}^g = \sigma_{ij}^1$  with  $g \approx 0$  as an approximation or  $g = 0$  in the case of an *anti-plane* brittle rupture propagating with shear-wave velocity or of an *in-plane* brittle rupture propagating with Rayleigh-wave velocity, respectively, we get

$$E_s = \frac{1}{2} D_i^f n_j \Delta\sigma_{ij} S_0 = \frac{1}{2\mu} \Delta\sigma_{ij} M_{ij} \quad (64)$$

with

$$\Delta\sigma_{ij} = \sigma_{ij}^0 - \sigma_{ij}^1. \quad (65)$$

Ohnaka (1978) gives the following relationship for the seismic energy of a circular shear fracture propagating with the crack velocity  $v_c = 0.8 v_s$ :

$$E_s = \frac{M_o \overline{D_0}}{2R} \quad (66)$$

with  $M_o$  – scalar seismic moment,  $\overline{D_0}$  – static averaged dislocation and  $R$  – source radius. For rectangular shear fractures of length  $L$  and with unilateral fracture propagation a similar approximate relationship holds:

$$E_s \approx \frac{M_o \overline{D_0}}{3L} \quad (67)$$

and in case of partial incoherence

$$E_s \approx \frac{M_o \overline{D}}{L}. \quad (68)$$

Further,  $E_s$  can be determined directly by integrating over the displacement field. It holds

$$E_s = \sum_k \int_{-\infty}^{\infty} dt \int_S dS \rho v^{(k)} \dot{u}_i^{(k)} \dot{u}_i^{(k)} \quad (69)$$

with  $S$  – a surface surrounding the source,  $\rho$  – density distribution on this surface,  $\dot{u}_i^{(k)}$  – velocity of ground motion. The sum is over all kinds of waves which leave the volume enclosed by the surface  $S$  with the velocity  $v^{(k)}$ . However, one has to take into account that on the way from the source to  $S$  part of the energy has already been transformed into heat by inelastic effects of wave propagation.

Equation (69) forms the theoretical background for the simple relationship between seismic energy and magnitude  $M$

$$\log E_s = a M + b \quad (70)$$

which is based on rather simple assumptions. Nevertheless, the corresponding relationship given by Gutenberg and Richter (1956) is

$$\log E_s[J] = 1.5 M_s + 4.8 \quad (71)$$

with  $M_s$  – surface wave magnitude (see 3.2.5.1). Equation (71) has proven to yield rather good estimates of  $E_s$ . More details on direct energy determination based on digital broadband recordings is outlined in 3.3.

## Acknowledgments

The authors acknowledge with thanks the fruitful discussions with Rongjiang Wang and Dietrich Stromeyer of the GFZ Potsdam and careful reviews by George Choy and Günter Bock <sup>‡</sup>. Their suggestions have helped to improve the first draft of this information.

## 1 Introduction

Besides location the magnitude is the most frequently determined and important parameter to characterize a seismic source and for earthquake statistics, aimed at assessing seismic activity and hazard, even the most important one. Classical magnitudes are based on the measurement of amplitudes and periods of seismic waves which also allow inferences on the structural and physical properties of the propagation medium. The usefulness of amplitude, period and magnitude data for application and research essentially depends on their long-term availability, homogeneity, reproducibility, compatibility and reliability. But these properties require globally agreed and applied measurement, calculation and data representation (nomenclature) standards. Inconsistencies in these crucial aspects increase data scatter, may even results in systematic biases, wrong inferences and thus strongly reduce the value of such data. This the more so since it has become obvious that no single magnitude is able to characterize the “sizes” of an earthquake in all of their geometric, kinematic and dynamic aspects. Better characterization of different aspects of earthquake size, desirable in order to better anticipate associated earthquake effects, requires a complementary set of magnitude types. Although this is outlined in detail in sections 3.1.2, 3.2 and 3.3 of Chapter 3 we summarize here some of the essential related aspects in order to better appreciate the need for a sufficiently detailed and unambiguous magnitude nomenclature.

The effort by Gutenberg and Richter (1954) to classify in “Seismicity of the Earth” earthquakes of different size by just ONE unspecified magnitude value  $M$  was one of the outstanding seismological milestones of the 20<sup>th</sup> century. It is now recognized, however, that a relative-size classification by a single type of magnitude implicitly presupposes an over-

simplified assumption of the similarity of the source process of all earthquakes and thus of their spectra, as, e.g., in Figure 1. The condition of source similarity (see section 3.3.1 of Chapter 3) holds only under certain conditions of geometric and dynamic similarity, such as constant stress drop  $\Delta\sigma$ . But for individual earthquakes  $\Delta\sigma$  may vary by several orders of magnitude and thus the corner frequency  $f_c \sim (\Delta\sigma)^{1/3}$  of the source spectrum up to a factor of 10 or even more. This means, however, that for a given static seismic moment or rupture “size” the ratio between released high and low frequency energy and thus the earthquake’s potential to cause shaking damage or to generate a tsunami is not constant. Therefore, magnitudes based on amplitudes measured in either the long-period or more medium to short-period range of the source spectrum may be rather different and thus the conclusions with respect to the size or “strength” of an earthquake and its related hazard potential (e.g., Choy and Kirby, 2004; Di Giacomo et al., 2008 and 2010; Bormann and Di Giacomo, 2011).

Abe and Kanamori were aware of this and therefore “decomposed” the Gutenberg-Richter (1954) and later published unspecified  $M$  for large earthquakes on the basis of Gutenberg’s original note pads and other sources into the original Gutenberg (1945a) 20 s surface-wave magnitude  $M_s$  and the more broadband 2-20s body-wave magnitude  $mB$  (Gutenberg and Richter 1956) [Abe (1981), (1982), and (1984); Abe and Kanamori (1979) and (1980)]. And the short-period “generic” magnitudes such as teleseismic  $mb$  and local  $ML$ , which are based on amplitudes at frequencies in the range  $0.3 \text{ Hz} < f < 10 \text{ Hz}$ , reveal in their relationship to the long-period event magnitudes even more clearly such hazard relevant shifts in source spectra corner frequencies for equal seismic moments away from or towards frequencies that are of particular interest to earthquake engineers (see Figures 1 and 2 below).

**Figure 1 Left:** "Source spectra" of a simplified “omega-squared” model, modified according to Bormann et al. (2009). Plotted are the ground displacement amplitudes  $A$  for “average” seismic shear sources with constant stress drop  $\Delta\sigma = 3 \text{ MPa}$  as a function of frequency  $f$ , scaled to seismic moment  $M_0$  and the equivalent moment magnitude  $M_w$ . **Right:** The same as left, but for ground motion velocity amplitudes  $V$ , scaled to seismic moment rate and  $M_w$ .

Note that the maximum of seismic energy  $E_s \sim V^2$  is radiated around the corner frequency  $f_c$ . The open arrows point to the center frequencies on the abscissa at which the 1 Hz body-wave magnitude  $m_b$  and the 20 sec surface-wave magnitude  $M_s(20)$ , respectively, are determined. The horizontal interval bars mark the range of frequencies within which broadband body- and surface-wave magnitudes  $mB(BB)$  and  $M_s(BB)$  and the local magnitude  $M_L$  should be measured.

**Figure 2** Far-field displacement and (b) velocity source spectra scaled to seismic moment and moment rate, respectively, for a model earthquake with  $M_w = 6.5$  but different stress drop  $\Delta\sigma$  in units of MPa. The spectra were calculated based on the same model assumptions as in Figure 1. The inset in Figure 2 (b) shows the variation of the corner frequency  $f_c$  obtained according to the Brune (1970, 1971) equation  $f_c = c v_s (\Delta\sigma/M_0)^{1/3}$  in a wider range of  $M_w$  for varying  $\Delta\sigma$  in increments of one order between 0.1 and 100 MPa. (Copy of Fig. 2, p. 415 in Bormann and Di Giacomo, 2011, J. Seismology, **15** (2), 411-427; © Springer Publishers).

This questions the whole currently still dominating concept of the seismic hazard community of "unifying" magnitudes in earthquake catalogs to moment magnitudes with  $M_0$  being a purely static-geometric parameter of rupture size corresponding to the zero-frequency plateau amplitude in Figure 1. This neglects the "dynamic variability" of the individual rupture process which is reflected, e.g., in the position of the corner frequency towards higher frequencies for equal seismic moment (Figure 2) and in the empirically proven variability of the decay of spectral displacement amplitudes towards higher frequencies with slopes varying between about 1 and 5 for  $f \gg f_c$ . Moreover, for the majority of instrumentally recorded events no accurate direct seismic moment measurements are available. This necessitates to estimate inferior  $M_w$  proxies via often rather noisy empirical correlation relationships between proper  $M_w$  with classical magnitudes (see ISC-GEM project: Global Instrumental Earthquake Catalogue (1900-2009), Di Giacomo et al., 2013). No single value magnitude type, including the supposedly non-saturating  $M_w$ , will ever allow to quantify both the (geometric) "size" and the seismic radiation efficiency and thus the potential "shaking strength" of an earthquake. Some of the currently common  $M_w$  procedures do not even fulfill the primary justification for having  $M_w$  as a non-saturating complement/extension to  $M_s$  (compare  $M_{wp}$ ,  $M_{wb}$  and  $M_{wc}$  in Table 1).

Therefore, future improvements in seismic hazard assessment necessitate a multi-magnitude approach. But this requires a deeper understanding of the physical relevance of the different magnitude scales, of their mutual relationship, as well as more “clean” complementary high quality data that have been measured over long time spans according to internationally agreed standards or otherwise clearly defined procedures, linked to easily accessible documentation published with unique nomenclatures that allows to unambiguously identify and correctly use such data.

The classical generic magnitudes are ML (Richter, 1935), Ms (Gutenberg, 1945a; since 1967 using the IASPEI standard Ms formula according to Vaněk et al., 1962), mB (Gutenberg 1945 b and c) and mb (Engdahl and Gunst, 1966), both using the Gutenberg and Richter (1956) calibration function for mB although mb as a more band-limited and high-frequency magnitude means a physically different thing. According to Figure 1 these “generic” magnitudes cover the range between 3 and 9 reasonably well. They are also the most frequently measured and at data centers collected magnitudes, with the exception of mB. Despite its fundamental importance (see Chapter 3, section 3.2.5.2) the determination of mB had been terminated in most parts of the world with the deployment of the narrowband instrumentation of the World-wide Seismic Standard Network (WWSSN) with peak magnifications between 1 and 2 Hz and 10 to 20 s, respectively (see Chapter 3, Fig. 3.20).

However, the procedures for measuring “generic” mb and Ms have not been so unique as global standards would have required for so widely used magnitudes. Different recording responses, measurement time windows after the P-onset and calibration functions were applied at different agencies or changed with time, resulting in increased data scatter, some systematic distance and/or magnitude-dependent biases and also in mixing of sometimes incompatible data. E.g., in the extreme case of the great Sumatra-Andaman Islands Mw9.3 earthquake of 26 December 2004 the following values for mb were reported by some of the leading seismological agencies: mb(IDC/CTBTO) = 5.7, mb(CENC, China) = 6.4, and mb(NEIC) = 7.2. Such differences for magnitudes of the same type and code name are not acceptable. Less dramatic but still significant are both distance- and magnitude-dependent biases up to 0.3-0.5 m.u. when using the IASPEI standard Ms formula, which had been derived for scaling A/T ratios in a wide range of periods between 2 and about 25 s, for scaling  $20 \pm 2$  s surface waves only. Facts, causes and the effects of lacking standards have been outlined and discussed in detail in Chapter 3.

Besides these classical magnitudes, which have been determined already for decades, mostly from analog records, others, such as the moment magnitude Mw and the energy magnitude Me, require digital broadband recordings and their spectral analysis or integration in the time-domain. Up to now they have been regularly determined only by a few specialized data centers. However, the broader use of these modern magnitude concepts is rapidly growing.

Short-comings of the current procedures to determine and annotate classical and also newly proposed magnitudes are, e.g.:

- Although already earlier IASPEI recommendations, published in the old Manual of Seismological Practice (Willmore, 1979), aimed at
  - expending and homogenizing magnitude measurements and nomenclature,
  - determining magnitudes from all seismic waves and component readings for which calibration functions are available,

- indicating the type of instruments and component on which the parameter readings (amplitudes, periods and/or duration) for a given magnitude value were made, these recommendations have become common practice only in a few countries;
- Body-wave magnitudes are nowadays determined from *vertical component* P-waves only although Gutenberg and Richter (1956) published body-wave calibration functions  $Q(\Delta, h)$  for both vertical and horizontal component readings of P and PP as well as for horizontal component readings of S;
- mb has been determined since the 1960s at “western” data centers and most stations and networks only from *short-period* recordings although the body-wave Q-functions have been derived mainly from medium- to long-period, more or less broadband recordings. Only some “eastern” countries, such as the former Soviet Union and its allies, or now in Russia, and in China, have seismograph networks continued to determine the classical Gutenberg and Richter (1956) medium-period broadband magnitude mB ( $m_B$ ) as well;
- Some other specialized international data centers such as the IDC of the CTBTO use for mb and Ms determination other than the common filter responses, measurement time-windows and/or calibration functions, resulting in the more or less strong incompatibility of their mb and/or Ms values (for comparison of mb(IDC) and mb(NEIC) see Murphy and Barker, 2003; Granville et al., 2002 and 2005; Bormann et al., 2007 and 2009);
- Currently still dominating “generic” magnitude nomenclature provides no hints to data users about such possible incompatibilities of magnitudes of supposedly the “same kind”;
- Calculating event mb averages, as done, e.g., at the ISC for many years from such incompatible NEIC and IDC mb data with an average (although magnitude-dependent) bias of about 0.4 m.u. is incorrect;
- Long-term continuity of classical standard magnitudes is a matter of high priority and necessitates proper scaling of modern magnitudes based on digital data with their forerunners that were based on analog data analysis. This has not always been done. Jumps in detection thresholds and catalog completeness due to unknown or not properly documented changes in measurement procedures may result in wrongly inferred changes of the relative frequency of occurrence of weaker and stronger earthquakes and be misinterpreted as changes in the seismic regime and the time-dependent seismic hazard (see case study for Southern California Ml by Hutton and Jones, 1993; also Habermann, 1995). This is not acceptable.

In order to overcome or at least mitigate these problems IASPEI established in 2001 within its Commission on Seismic Observation and Interpretation (CoSOI) a Working Group on Magnitude Measurements (in the following for short termed the WG). It has been entrusted with critically screening the most common procedures of amplitude measurement and magnitude determination practiced at seismic stations and various data centers and proposing measurement and nomenclature standards. Its members were: J. Dewey and P. Bormann (co-chairs), P. Firbas, S. Gregersen, A. Gusev, K. Klinge, B. Presgrave, L. Ruifeng, K. Veith, W.-Y. Kim, H. Patton, R. A. Uhrhammer, I. Gabsatarowa, J. Saul, and S. Wendt. The essential results are summarized below.

## 2 Seismic parameter data formats

The Willmore (1979) proposal for reporting magnitude parameter data was still based on the classical and costly telegraphic format. Modern seismic networks can provide far more information and low-cost e-mail transmissions and data exchanges via Internet have eliminated the restrictions and high costs of old telex messages. Consequently, as outlined in Chapter 10, most seismic parameter data have been stored and exchanged since at least 1990 in modern formats that are more complete, simpler and usually more transparent than the telegraphic format. But only rather recently agreement has been reached on some modern generally accepted standard formats for reporting parameter data.

A major step forward in this direction was made by the Group of Scientific Experts (GSE) organized by the United Nations Conference on Disarmament. It developed GSE/IMS formats (see Chapter 10, section 10.2.4) for exchanging parametric seismological data in tests of monitoring the Comprehensive Test Ban Treaty (CTBT). Seismological research, however, has a broader scope than the International Monitoring System (IMS) for the CTBT. Therefore, a new **IASPEI Seismic Format** (ISF; <http://www.isc.ac.uk/standards/#dataformats>), which is compatible with the IMS format but with essential extensions, has been developed and adopted by the Commission on Seismological Observation and Interpretation (CoSOI) of the International Association of Seismology and Physics of the Earth's Interior (IASPEI) at its meeting in Hanoi, August 2001. Examples for ISF compatible parameter data plots are given in the Information Sheet IS 10.2 and in Table 1 below. Both the International Seismological Centre (ISC) and the USGS National Earthquake Information Center (NEIC) present, exchange and archive their parameter data in the ISF format.

With respect to magnitude data, however, the ISF format limits the length of the magnitude names (nomenclature) to 5 letters/symbols. Further specification is however possible in combination with the related “amplitude phase name” which allows for more letters/symbols.

Since 2001 new developments have been introduced due to technology changes. The introduction of XML, i.e., an Extensible Markup Language, allows to present hierarchic structured data in form of [text](#) files and thus enables a platform and implementation independent exchange of data between computer systems, especially via [Internet](#). This again resulted in the requirement of a standard scheme for the representation of seismological parameter data. QuakeML, initiated and maintained by the Swiss Seismological Service, is such a collaborative effort. Detailed documentation and contact addresses are accessible via <https://quake.ethz.ch/quakeml/QuakeML>. The latest version 1.2 has been released only on 14 Febr. 2013 with the basic event descriptions mostly stable as of this writing but with the related metadata presentation still being under development.

QuakeML does not specify a magnitude or a magnitude name and its length. This is considered to be the duty of other standards. In QuakeML a magnitude name may be arbitrarily long. Rather, QuakeML permits to describe in detail how the amplitudes, periods, duration or other magnitude-relevant parameters have been measured by whom, when, where, and how, i.e., according to which procedure. QuakeML also allows to describe how the station and event magnitudes have been calculated from the measurement parameters, taking into account station counts and azimuthal gaps, the evaluation mode and statistics, how moment tensors have been determined etc. For details see sections 3.5.5 to 3.5.9 in Euchner and Schorlemmer (2013).

This latest development has to be closely followed up further because it might offer a comfortable and flexible complement to the limitations of the fixed ISF magnitude format for allowing the badly needed sufficiently detailed and unique description of the procedure of magnitude determination in the metadata.

### 3 IASPEI standard magnitudes

By May 2002, the WG reached the following first general understanding:

- the “generic” magnitudes ML, mb and Ms are most common, and related data for their determination are regularly reported by seismic stations and networks/arrays to international data centers;
- these “generic” magnitude names are widely accepted and applied by a diversity of user groups. Therefore, their **names should be kept when reporting magnitude data to a broader public.**
- this nomenclature is also considered to be adequate for many scientific communications, but **on the understanding that these magnitudes have been determined according to well established rules and procedures;**
- the WG realized, however, that different data producers make their related measurements for determining these magnitudes on records with different response characteristics and bandwidths, on different components and types of seismic waves and sometimes also use different period and measurement time windows. This increases data scatter, may produce baseline shifts and prevents long-term stable, unique and reproducible magnitude estimates that are in tune with original definitions, earlier practices and inter-magnitude conversion relationships;
- this situation is no longer acceptable, therefore, the WG felt a **need to introduce an obligatory more “specific” nomenclature** for reporting magnitude, amplitude (and related period) measurement data for databases and for use **in scientific correspondence and publications in which the ambiguity inherent in the “generic” nomenclature might cause misunderstanding;**
- the WG notes that the recently accepted IASPEI Seismic Format (ISF, see section 10.2.5 of Chapter 10) and the flexibility of internet data communication allow such specifications in nomenclature and even complementary remarks to be reported to international data centers, and to store and retrieve such data from modern relational databases.

Therefore, the WG proposed within its mandate:

- a) standard measurement procedures for amplitude-based magnitudes that agree as far as possible and reasonable with magnitudes of the same type that have been measured for decades from analog seismograms according to original definitions,
- b) that promote the best possible use of the advantages of digital data and processing,
- c) a unique nomenclature for these standard magnitudes and related amplitude data which is compatible with the IASPEI Seismic Format (ISF) and allows an unambiguous discrimination between standard and non-standard data;

- d) a questionnaire for dissemination (and deposition of the responses) by the ISC to seismic parameter data reporting stations and agencies on their specific procedures for recording and analyzing data relevant for magnitude calculation (see IASPEI, 2013: [http://www.iaspei.org/commissions/CSOI/Summary\\_WG\\_recommendations\\_20130327.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG_recommendations_20130327.pdf) and Annex 1 in IS 3.4)

with the main aim to

- e) minimize bulletin magnitude biases that result from procedure-dependent single-station or network magnitude biases;
- f) increase the number of seismological stations and networks with well-defined procedures;
- g) avail at the ISC as the final authoritative depository of the most complete and accurate seismological parameter data set also a directory of all standard and agency-specific procedures and nomenclatures;
- h) increase essentially the accuracy, representativeness, homogeneity and long-term global compatibility of magnitude data and their usefulness for seismic hazard assessment and research.

First recommendations for standard magnitude measurement procedures were published by IASPEI (2005). The latest update is posted under IASPEI (2013). The following standard types of magnitudes have been proposed and the procedures of their determination been specified. For more details, also on filter parameters and calibration functions, distance ranges of applicability, admissible deviations etc., see NMSOP-2, Chapter 3, sections 3.2.3.2, 3.2.4, 3.2.5 and IS 3.3:

- Local magnitude **ML** according to the Hutton and Boore (1987) formula measured on simulated Wood-Anderson records according to the parameter specifications of Uhrhammer and Collins (1990);
- Regional magnitude  $mb(Lg) = \mathbf{mb\_Lg}$  based on amplitude measurement of the Lg phase in a defined group-velocity window on WWSSN-SP simulated records;
- Short-period body-wave magnitude **mb** by measuring on simulated WWSSN-SP records the largest amplitude with periods  $< 3$  s in the whole P-wave train prior to PP and calibrating it with the Gutenberg and Richter (1956) calibration function for vertical component P waves;
- Broadband body-wave magnitude  $mB(BB) = \mathbf{mB\_BB}$  by measuring the largest velocity amplitude in the whole P-wave train on velocity-broadband records in a wide period range between 0.2 s and 30 s and calibrating it as for mb;
- Surface-wave magnitude  $Ms(20) = \mathbf{Ms\_20}$  by measuring the largest amplitude in the Rayleigh-wave train on simulated long-period WWSS-LP records at periods between 18 s and 22 s and calibrating A/T with the IASPEI standard Ms formula according to Vaněk et al. (1962) in the distance range between  $20^\circ$  and  $160^\circ$ ;
- Surface-wave magnitude  $Ms(BB) = \mathbf{Ms\_BB}$  by measuring the largest velocity amplitude in the Rayleigh-wave train on broadband velocity records in a wide range of periods between 3 s and 60 s in the wider distance range between  $2^\circ$  and  $160^\circ$  and calibrating them with the Vaněk et al. (1962) formula for Ms. This formula had in fact been developed on the basis of data in this wider range of period and distances.

With the exception of standard ML, which is measured on single horizontal components, not vector summed but each counted as an individual magnitude datum, all other standard magnitudes are measured on vertical component records only.

For international data exchange and archiving the magnitude names (nomenclature) should be written in the maximum 5-letter code (as above in **bold**) reserved in the ISF format for magnitude data.

In order to associate unambiguously the measured amplitudes and periods with the respective standard magnitudes the following standard nomenclature in the ISF format has been agreed upon for the so-called “amplitude phase names” (which may exceed 5 letters):

IAML, IAmb, IAmb\_Lg, IAMs\_20, IVmb\_BB and IVMs\_BB.

I stands for IASPEI International standard, A for displacement amplitude in units of nm and V for velocity amplitude in nm/s.

#### 4 Magnitude and amplitude nomenclature applied by the USGS-NEIC

The USGS/NEIC runs since 2006 its new fully automatic HYDRA location and analysis system. It measures routinely in experimental mode the amplitudes and periods related to all recently recommended IASPEI standard magnitudes according to the filter and measurement procedures outlined in IASPEI (2013) and IS 3.3. These data are presented in the event and station parameter plots according to the recommended standard nomenclature (see previous section) for amplitude phase names and related magnitudes (Table 1).

Additionally, HYDRA measures some agency-specific magnitudes, amongst them several versions of moment magnitude based on broadband body or surface waves (Mwb according to ???, Mwc according to ???, and Mwp according to ???), a time-domain, variable-period surface-wave magnitude Ms(VMAX) for application at regional and teleseismic distances according to a procedure proposed by Bonner et al. (2006) and a not specified average event magnitude M out of all these data (Table 1). All these magnitudes are given in the *maximum 5-letters* ISF format, which required to shorten, e.g., Ms(VMAX) to Ms\_VX.

**Table 1** Cut-out from an event and station parameter plot in IMS1.0/ISF parameter format produced by the USGS/NEIC HYDRA automatic location and analysis system.

This way of an unambiguous presentation and annotation of magnitude and related amplitude data may serve as a good example for other seismological agencies as well, provided that the data users are somehow guided, e.g., via some explanatory pages that accompany data reports or bulletins and link to relevant documents/publications in which the respective procedures and - hopefully - also the relationship of this type of magnitude to other well established and widely used magnitudes are explained (see next section 5). Regrettably, the parameter data plot in Table 1 does not allow to say in which component the measurement has been made. One just has to know that all above amplitudes and magnitudes have been measured exclusively on the vertical component. However, standard ML should be measured on either the N or E or both components and any teleseismic S-wave amplitude or magnitude measurement, currently still greatly disregarded despite its undoubted scientific importance (see section 6), should preferably be made on horizontal components as well. Even the standard magnitude “amplitude phase names” do not yet account for a differentiation between vertical and horizontal component measurements.

## 5 Magnitude nomenclature reported to the ISC

The ISC (2013) Bulletin Summary for January-June 2010 includes the description of the upgraded new ISC procedures and the nomenclature for agency-specific magnitudes reported to the ISC. The latter are outlined in detail in Tables 9.6 and 9.7 of the ISC (2013) Bulletin Summary. For the period January-June 2010 **148 agencies contributed 29 different types of magnitudes**. This is due to the different seismological practices both at regional/national and global level in computing magnitudes from a multitude of combinations of wave types, period and amplitude measurement standards, distance ranges, instruments, components, algorithms etc. They are listed along with the agency codes and the number of earthquakes for which these magnitudes have been determined. Their main features are presented in tabulated form together with references to documents in which the procedure and/or data peculiarities are outlined. Table 2 is an abridged sample of the types of magnitudes contained in the ISC Bulletin for the time January-June 2010.

In Table 2 the proper IASPEI standard magnitude names according to the finally in 2011/2013 agreed nomenclature have not yet been used and also not yet been reported to the ISC. However, in a special investigation Bormann et al. (2009) compared for large event data sets in the wide magnitude range  $4 < M < 9$  all types of traditional Chinese magnitudes, measured at the China Earthquake Network Centre (CENC), with independently measured related IASPEI standard magnitudes. E.g., Ms7 in Table 2 is measured on vertical component

records with a WWSSN-LP response, as the standard  $M_s(20)$ . But, in contrast to the latter, which is measured only at periods between 18 s and 22 s and in the distance range  $20^\circ$ - $160^\circ$ ,  $M_s7$  is based on surface-wave displacement amplitude maxima with periods  $T > 6$  s measured in the distance range  $3^\circ$ - $177^\circ$ . Nevertheless, independent  $M_s7$  and  $M_s(20)$  for the same events agreed almost perfectly within the tolerance limit of 0.1 m.u. set by the WG. The orthogonal regression relationship is  $M_s7 = 0.99M_{s\_20} + 0.14$  with a standard deviation of  $\pm 0.20$  m.u.. The latter is typical for high-quality  $M_s$  determinations. Thus,  $M_s7$  and  $M_{s\_20}$  are fully compatible and new  $M_{s\_20}$  could be merged with older  $M_s7$  data without any loss in quality or increase in data scatter, which means assured data continuity.

**Table 2** Examples of magnitudes reported to the ISC by data contributing seismological stations or agencies for the Summary of the ISC Bulletin January-June 2010 (ISC, 2013). All references cited in the table, and agency abbreviations, are given in ISC (2013) but those typed in *Italics* also in the reference list to this IS.

| Magnitude type | Description                                                      | References                                                         | Comments                                                                     |
|----------------|------------------------------------------------------------------|--------------------------------------------------------------------|------------------------------------------------------------------------------|
| M              | Unspecified magnitude type                                       |                                                                    | Often related to real or near-real time magnitude estimations                |
| mB             | Broad-band body-wave magnitude                                   | <i>Gutenberg (1945b,c); IASPEI (2005); Bormann and Saul (2008)</i> |                                                                              |
| mb             | Short-period body-wave magnitude                                 | <i>IASPEI (2005)</i>                                               | Classical mb computed from station between $20^\circ$ - $100^\circ$ distance |
| mb1            | Short-period body-wave magnitude                                 | IDC (1999) and references therein                                  | Reported only from IDC; it includes also station below $20^\circ$ distance   |
| mb1mx          | Maximum likelihood short-period body-wave magnitude              | Ringdal (1976); IDC (1999) and references therein                  | Reported only from IDC                                                       |
| mbtmp          | short-period body-wave magnitude with depth fixed at the surface | IDC (1999) and references therein                                  | Reported only from IDC                                                       |
| mbLg           | Lg-wave magnitude                                                | <i>Nuttli (1973); IASPEI (2005)</i>                                | Reported only by MDD and by other North American agencies as MN              |
| Mc             | Coda magnitude                                                   |                                                                    |                                                                              |
| MD (Md)        | Duration magnitude                                               | <i>Bisztricsany (1958); Lee et al. (1972)</i>                      |                                                                              |
| ME (Me)        | Energy magnitude                                                 | <i>Choy and Boatwright (1995)</i>                                  | Reported only by NEIC                                                        |
| MJMA           | JMA magnitude                                                    | <i>Tsuboi (1954)</i>                                               | Reported only by JMA                                                         |
| ML (MI)        | Local (Richter) magnitude                                        | <i>Richter (1935); Hutton and Boore (1987)</i>                     |                                                                              |
| MLSn           | Local magnitude calculated off $S_n$ phases                      | Balfour et al. (2008)                                              | Reported by PGC only for earthquakes west of the Cascadia subduction zone    |

|         |                                                                |                                                              |                                                                                                                                 |
|---------|----------------------------------------------------------------|--------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------|
| MLv     | Local (Richter) magnitude computed from the vertical component |                                                              | Reported only by DJA and BKK                                                                                                    |
| MN (Mn) | Lg-wave magnitude                                              | <i>Nuttli (1973); IASPEI (2005)</i>                          | Also reported as mbLg from MDD                                                                                                  |
| MS (Ms) | Surface wave magnitude                                         | <i>Gutenberg (1945a); Vaněk et al. (1962); IASPEI (2005)</i> | Classical surface wave magnitude computed from station between 20°-160°                                                         |
| Ms1     | Surface wave magnitude including                               | IDC (1999) and references therein                            | Reported only by IDC; it includes also stations below 20° distance                                                              |
| mslmx   | Maximum likelihood surface wave magnitude                      | Ringdal (1976); IDC (1999) and references therein            | Reported only by IDC                                                                                                            |
| Ms7     | Surface wave magnitude                                         | <i>Bormann et al. (2007)</i>                                 | Reported only by BJI and measured in the distance range 3°-177° on records of a Chinese-made seismograph with WWSSN-LP response |
| MW (Mw) | Moment magnitude                                               | <i>Kanamori (1977); Dziewonski et al. (1981)</i>             |                                                                                                                                 |
| Mw(mB)  | Proxy Mw based on mB                                           | <i>Bormann and Saul (2008)</i>                               | Reported only by DJA and BKK                                                                                                    |
| Mwp     | Moment magnitude from P-waves                                  | <i>Tsuboi et al. (1995)</i>                                  | Reported only by DJA and BKK and used for rapid response purposes                                                               |

Not as perfect is the agreement between Ms(CENC) and Ms(20), measured at different components, period ranges, record responses and with a constant difference in the calibration function ( $\Delta M = 0.25$  m.u.). And the average differences between other combinations of similar types of magnitude measurement depend on magnitude, ranging from small to large magnitudes for mB(CENC) and mB(BB) from  $\Delta M = -0.3$  to  $0.0$  m.u., for Ms(CENC) and Ms(BB) from  $\Delta M = 0.0$  to  $+0.4$  m.u., and for mb(CENC), which is measured only within the first 6 s after the P-wave arrival, the difference to standard mb may reach at the largest earthquakes even  $-1$  m.u. It is just this kind of procedure-dependent data incompatibilities in international data exchange, which the measurement standards aim to eliminate, thus reducing data scatter and improving the global compatibility of magnitude estimates.

This experience from China shows that it is highly desirable that seismic stations/agencies reporting data to the ISC or to other regional or global seismological data centers compare - in conjunction with the introduction of the new IASPEI standard magnitudes - for a sufficiently large and representative set of seismic records from events in a wide range of magnitudes and distances the results of their traditional magnitude procedures with those according to the new IASPEI standard procedures. A suitable representative test data set can be downloaded via IS 3.4, which gives also guidelines for carrying out such a test by using the SEISAN software. If the average absolute differences turn out to be within  $0.1$  m.u. then the traditional procedure yields in fact IASPEI standard compatible results.

Sometimes this may be the case even if some procedural details, such as the applied filter responses, differ significantly. An example is given in IS 3.3 (Figures 10 and 14) comparing

Ms<sub>20</sub> measured on either SRO-LP or WWSSN-LP responses. Analysis software which has an SRO-LP simulation filter implemented, such as Seismic Handler Motif (SHM), could then be used as an even better alternative for Ms<sub>20</sub> determination, because the measured A and T are within acceptable limits of measurement accuracy identical with those measured on WWSSN-LP records and can thus be reported with the standard amplitude nomenclature IAMs<sub>20</sub>. But because of the generally better SNR of SRO-LP records one is able to measure even more surface-wave magnitudes, especially from weaker events. Moreover, also automatic A and T measurements are less error-prone because of the less noisy and thus simpler waveforms in SRO-LP filtered records (see Figure 13 b in IS 3.3). This, however, is not a rule. In other cases of magnitude measurements in other frequency ranges and on other seismic phases already smaller changes in recommended measurement parameters may result in much larger magnitude differences.

In any event, the ISC as the most representative, complete and accurate final depositary of seismological parameter data should be informed by all its data contributing stations/agencies about the details of their procedures for recording, measuring and calibrating their magnitude data. In order to assure sufficient completeness and compatibility of provided information, the IASPEI/CoSOI WG has developed a questionnaire which is annexed to both IASPEI (2013) and (as Annex 2) to IS 3.4. Based on such information and the results of comparative measurements with traditional agency and new IASPEI standard procedures the number of agency specific entries in Table 2 is likely to shrink significantly with the global introduction of the IASPEI (2013) measurement standards.

## 6 Proposal for a more generalized unique nomenclature for amplitude and magnitude data

In order to assure future IASPEI-authorized standards annotation and reporting of measurements for amplitude-based seismic magnitudes, the WG on magnitude measurements had agreed already a decade ago on the suitability of a more general systematic nomenclature for presenting amplitude and magnitude data in a unique manner (see IS 3.2 in NMSOP-1, in Bormann, 2002 and 2009). It is based on recommendations of the Sub-Commission on Magnitudes of the Commission on Practice made at the Joint General Assembly of the IASPEI/IAVCEI Meeting in Durham 1977. These recommendations aimed at measuring and reporting magnitudes in an unambiguous manner for all seismic phases and from all component readings for which magnitude calibration functions according Richter (1935, 1958), Gutenberg and Richter (1956) and Vaněk et al. (1962) were available (see first bullet-point paragraph on page 4). The reason that Gutenberg and Richter (1956) proposed besides P waves also PP and S for magnitude determination and also amplitude measurements from vertical and horizontal components were that

- medium to long-period PP is usually the largest longitudinal wave in the core shadow of P beyond 100°, up to 180°, allowing more reliable mB event estimates, based on more stations than with P waves alone;
- medium to long-period S is usually the largest secondary body-wave phase after P with amplitudes much larger than that of P and with a radiation pattern about 45° off that of P (see section 3.4.1 of Chapter 3). This again assured more independent magnitude data and, when averaged with those from P wave readings, data that are much less affected by the radiation pattern of the seismic source, which may in the

case of only a few stations with P-wave readings and insufficient azimuthal coverage produce rather biased magnitude estimates;

- teleseismic S-waves have generally their largest amplitudes in the horizontal components, and horizontal PP amplitudes are also relatively large or even larger than those of P, and, because of different take-off angle, also source mechanism dependent. Moreover, at Gutenberg and Richter's times stable long-period vertical component recordings were not yet as commonly available as nowadays.

During recent decades the virtual global seismic network of high-resolution stable broadband recordings has grown tremendously. Therefore, an insufficient number of stations with potential amplitude readings and the need for independent amplitude readings from PP and S has become much less of a problem for a reliable magnitude determination than in the past. However, S-wave amplitude, period and/or ground velocity readings and reporting to the international data centers are still grossly neglected at many observatories/networks (see Chapter 1) although they are highly desirable for improving the shear-wave attenuation model of the Earth down to shorter periods and thus with higher spatial resolution and with larger penetration depths than possible with surface waves. But when measuring S amplitudes they could be used for additional S-wave mB estimates as well with the advantage of reducing possible P-wave station mB biases in the case of inappropriate azimuthal station coverage. But then it would be desirable to clearly differentiate between mB based on P, S and/or PP.

For the original proposal of a more systematic unique magnitude nomenclature see Willmore (1979; p. 124)) and its extension in IS 3.2 of NMSOP-1 (Bormann, 2002 and 2009. An example along these lines has been given for a strong Mongolia earthquake in Tab. 3.1 of Chapter 3.

In view of the now reached agreement on standard measurement procedures and a unique nomenclature for 6 widely determined types of magnitude as well as the general trend to measure related amplitudes, with the exception for ML, on vertical component records only, this proposal may at present appear to be obsolete. In section 5 of this IS it has also been shown that agencies or stations reporting magnitudes to international data centers or publishing them in their bulletins may define their own ISF format compatible magnitude names. They could be unique and unambiguous provided that they are accompanied, as in Table 2, by references to publications/documents which describe in detail the procedures for recording, filtering, measuring, and calibrating these magnitudes, in a similar way as the IASPEI standard magnitudes have been defined in IASPEI (2013) or IS 3.3. Moreover, it has to be assured that other data producers that apply the same procedures use also the same nomenclature. If handled this way then it is indeed the best way to keep data centers and external data users fully informed. This avoids mixing incompatible data and biased conclusions. Precondition is, however, that all data producers really make their agency-specific ways of magnitude determination, hopefully together with some information on how there magnitudes relate to other well established and/or IASPEI standard magnitudes of the same type, publicly available via their national or regional/global data centers (for questionnaire see references in section 5).

Nevertheless, we will give below in Table 3 a few examples for another way of designing unique magnitude names, also for other than the now common phases, components, record responses and calibration functions. It is based on the earlier version presented in I.S 3.2 of NMSOP-1. However, the current upgrade allows also to differentiate between magnitudes

based on displacement amplitudes  $A$  and broadband velocity amplitudes  $V$  and the instrument code is no longer put in brackets. Moreover, since  $V$  stands now for velocity the vertical component code is now  $Z$ , as in the Gutenberg-Richter (1956) calibrations diagrams.

Further, one has to know that Willmore (1979) presents in Fig. 1.1 the following standard response classes for analog seismographs: Type A (short-period, A1-A4), B (long-period, B1-B3), C (displacement broadband Kirnos), D (velocity broadband 1-100 s), and E (classical Galitzin) besides the classical Wood-Anderson (WA) response. These responses still resemble widely used responses of modern digital records or of common synthetic filter outputs derived therefrom (e.g., A1 = Benioff-SP, A2 = WWSSN-SP, A3 = French APX system, A4 = Russian SKM-3 seismograph; B1 = WWSSN-LP, B2 = French system, B3 = high-gain HGLP system; C = Kirnos seismograph). The latter has two widely used versions: C1 = SK - corner period of 10 s and C2 = SKD – 25 s, with C1 being a standard filter at CENC for Chinese mB and Ms measurement and C2 being a standard filter in SHM and Pitsa software because of the superiority of C2 records in seismic phase recognition (see Chapter 11). And the Willmore (1979) standard response D covers the main period range of modern velocity broadband seismographs, which is between 1 and 100 s. Therefore, we use these class symbols in order to illustrate the filter/seismograph type specification in the proposed generalized magnitude nomenclature. It may be replaced or complemented by any other unique specified filter/seismograph response symbol. Along these lines we propose in Table 3 just a few magnitude names for readings of maximum amplitudes of different seismic phases made on horizontal or vertical component records of such basic standard types of seismographs/filters and calibration functions and compare them with respective “generic” magnitude names. As a general unique magnitude name we propose **MXYFC** with

- **M** being the general symbol for magnitude.;
- **X** the symbol name of the seismic phase on which the amplitude and periods for the respective magnitude have been measured, e.g., P, S, PP, Lg, PKP;
- **Y** the component on which amplitude and period have been measured, e.g., N for the north-south, E for the east-west, Z for the vertical and H – for the vectorially combined horizontal component;
- **F** the symbol for the filter/seismograph response on the record of which the amplitude and period have been measured;
- **C** the symbol for the calibration function which has been applied to calculate the respective magnitude based on the measure ground motion amplitudes and periods.

However, in the case that the considered magnitudes have been calculated on the basis of other measurement parameters or procedures such as duration, spectra, waveform fitting and inversion, tsunami run-up or wave height measurements, the MXYFC nomenclature is not appropriate and should better be replaced by MAG (MAgency) or MAU (MAuthor) with reference being available for full procedural details.

Along these lines a few examples are presented in Table 3, using the following additional abbreviations:

A-E seismograph/filter type classes according to their definition in Willmore (1979) and outlined above, with a number added if there are several common types within a given class. E.g., one could give the NEIC PDE filter and the IDC/CTBTO filter used for short-period parameter readings, which differ from A1-A4 (see Figure 3 in IS 3.3) the numbers A5 and A6, respectively.

|          |                                                                                                                                                                                                                                                                                                                                                                       |
|----------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| WA       | Wood-Anderson horizontal-component seismograph with displacement-proportional response in the period range 0.1 to 0.8 s;                                                                                                                                                                                                                                              |
| RO       | stands for the long-period Seismological Research Observatory (SRO-LP) response (see Figure 10 in IS 3.3);                                                                                                                                                                                                                                                            |
| $\Delta$ | epicentral distance as commonly used in calibration functions;                                                                                                                                                                                                                                                                                                        |
| h        | hypocentral depth;                                                                                                                                                                                                                                                                                                                                                    |
| L        | largest (relatively) long-period surface wave                                                                                                                                                                                                                                                                                                                         |
| Q        | at the end of the magnitude name stands for the respective Gutenberg and Richter (1956) calibration function $Q(\Delta, h)$ for either PZ, PH, PPZ, PPH, SH (see Figures 1a-c and Table 7 in DS 3.1 and for standard PZ also in tabulated form for all source depths with program description in PD 3.1);                                                             |
| $\sigma$ | at the end of the magnitude name stands for the Prague-Moscow (Vaněk et al., 1962, or Karnik et al., 1962) calibration function $\sigma(\Delta)$ for surface-wave readings of both LZ and LH; recommended as standard by IASPEI and used at both the NEIC and the ISC (in tabulated form as Table 4 in DS 3.1; as standard formula see Chapter 3, Eqs. (3.35 or 3.36) |
| C        | Stands for any other specific calibration function, e.g., RI for Richter (1958), HB for Hutton and Boore (1987) or VC for the Veith and Clawson (1972) calibration function $P(\Delta, h)$ used at the IDC/DTBTO (for details see DS 3.1).                                                                                                                            |

For magnitudes that have been determined from records of seismographs with other response characteristics than the standards A to D or WA and/or by using calibration functions other than  $\sigma(\Delta)$ ,  $Q(\Delta, h)$  or local scales properly linked to the original Richter  $M_L$  (ML) scale, this should be specified by giving filter type F and C in brackets, i.e.,  $M(F; C)$ , or by adding a complementary comment line with the name of the relevant author/institution or with a link to proper reference and documentation.

Amplitude data for identified seismic phases should be specified and reported to data centers in the following general format for non-IASPEI standard “amplitude phase names”: **AXYF** or **VXYF**:

with A = displacement amplitude in nm or V = velocity amplitude in nm/s  
and X, Y and F as defined above, e.g.:

- ASHB2 – horizontal component S-wave displacement amplitude on a WWSSN-LP record;
- APPZC2 – vertical component PP-wave displacement amplitude on a Kirnos SKD record;
- VPZD – vertical component P-wave velocity amplitude on type D record.

In the case that phase name, component, filter type and calibration function can be uniquely described by just one letter, then the general MXYFC nomenclature would perfectly match with the ISF 5-letter magnitude name format. This, however, is not possible for more than single letter phase names such as Lg, PP or PKP, in the case of using more specific responses within a standard response class (such as A1 or C2) and/or calibration functions that require more than one letter to describe them unambiguously. A few such examples have been added to Table 3 too, typed in *Italics*.

This dilemma remains as long as the most relevant current seismic standard data formats limit the length of magnitude names to 5 letters. A future extension might therefore be considered by IASPEI/CoSOI. As long as this is not the case, however, we can only recommend, that the component information and any specification within a considered response class is conveyed by the related magnitude “amplitude phase name”, as shown above. The type of calibration function used for calculating a specific type of magnitude from a compatible set of measured parameter data, however, has then to be documented in the metadata and/or in related generally accessible documentation as it has been done for the current IASPEI standard magnitudes. The same holds if some agency decides to measure amplitudes and periods not at the maximum of the respective phase waveform but within an arbitrarily fixed measurement time window after the phase first arrival, such as the 5.5 s window set by the International Data Centre (IDC) of the Comprehensive Test-Ban Treaty Organization (CTBTO). Such a combination of magnitude and amplitude phase name nomenclature or M(Agency) specification would limit also for non-standard magnitudes their names to match the ISF 5-letters magnitude code, e.g.:

- MPA in conjunction with APZA5 (previous NEIC PDE mb)
- MPPD in conjunction with VPPHD;
- MPPC in conjunction with APPZC2;
- MLgA in conjunction with ALgZA2;
- MPIDC with reference to procedure definition (e.g., section 17.4.2 of Chapter 17).

**Table 3** Preliminary proposal for specific magnitudes not measured and/or scaled according the recommended IASPEI (2013) standard and the equivalent “generic” magnitude names. The ambiguity of generic magnitude names is obvious.

| Specific                                   | Generic | Description                                                                                                                                                                                                                                                                                         |
|--------------------------------------------|---------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

| <i>MLZB1<math>\sigma</math></i><br>or<br><i>MLZRO<math>\sigma</math></i> | Ms | Rayleigh surface-wave magnitude from L readings in vertical component records of type <b>B1 = WWSSN-LP</b> , or SRO-LP, calibrated with the IASPEI standard $\sigma(\Delta)$ (cf. Eq. 3.35, or 3.36 in Chapter 3).<br><b>Equivalent with standard Ms_20</b> if measured at periods between 18-22 s. |

In the case that amplitudes have been measured on phases, components and with procedures according to the respective IASPEI magnitude standards (see section 2) then the IASPEI amplitude phase name nomenclature should be used instead, e.g., IAMB\_Lg or IVMs\_BB. For non-standard agency or author specific magnitudes, however, one should avoid any confusion with traditional generic or new standard magnitudes and generally use capital M as the unique magnitude symbol, followed by phase, component, filter and calibration function symbol as in Tab. 3, or, if this exceeds the 5-letters code, by the proposed abridge version MXF in conjunction with the respective more detailed amplitude phase names A(orV)XFn and the calibration function C specified in the metadata.

## 7 Author or agency specific magnitude nomenclature

Classical magnitudes based on not strictly standardized procedures still form the majority of available magnitude data for quite some time. This particularly applies to the three “generic” types of magnitudes, ML, mb and Ms. The majority of countries, using ML, have not yet been able to derive their own local/regional calibration functions that are properly scaled and tested with respect to the IASPEI standard. mb data, measured up to now (2013) and contained in national and international data bases, are still more or less a mixture of data measured with slightly different instrument responses within differently fixed or flexible measurement time windows. And also Ms data may differ by up to several tenths of magnitude units depending on the specific Ms procedure applied. Therefore, it is important that the new standards now clearly differentiate between Ms\_20 and Ms\_BB or any other type of Ms. **Any future use of the undifferentiated generic magnitude symbol Ms would be highly counter-productive**, not so much in publications to a broader public when accuracy matters less but **in any scientific publication and data base with relevance for future research**.

Regrettably, such a clear distinction between old (still mixed and thus more noisy or even incompatible) and new (standardized) ML and mb data is not yet possible because the IASPEI Working Group was unable to agree on specified non-generic IASPEI standard names for ML and mb. This persisting ambiguity between old generic and new standard magnitude data symbols may confuse in future users of both old and new data with respect to their compatibility, unless the distinction can be made on the basis of the related standard amplitude phase names IAML and IAMB for standard ML and mb in contrast to AML and Amb for non-standard versions of these two magnitudes.

For ML data that are used for relevant studies only within the considered regions and less frequent, if ever, for interregional comparison of compatibility (an exception see section 3.2.9.6 in Chapter 3), the generic ML nomenclature may be less of a problem as long as no interregional and border crossing seismic hazard assessment is based on such data. In order to reduce uncertainties in this respect we have presented in Table 2 of DS 3.1 MI formulas for 16 different regions world-wide together with information on their calibration to either the traditional Richter (1935) scale and Wood-Anderson records or to the new IASPEI standard formula (3.15) in Chapter 3 when using synthetic WA records. Moreover, in both NMSOP-1 (2002 and 2009) and NMSOP-2 (2012/13) we deliberately **use the more general symbol MI for local magnitudes. It may be changed to ML when the related formula for the region under consideration has been properly scaled to the IASPEI standard formula and procedure.** If not, it should be considered and also denoted as an area- or agency-specific formula MIAG if it is likely to produce average absolute differences  $> 0.1$  m.u. as compared to formula (3.15) in Chapter 3.

The multitude of currently used agency-specific magnitudes may be very confusing for users. Systematic inter-comparison between these formulas and the new IASPEI standards offers the chance to streamline, homogenize and reduce their number by agreeing on the circumstances under which these magnitudes have the same values as their IASPEI counterparts. In fact, in most cases a specific magnitude scale will agree on average with another magnitude scale at some appropriate value, e.g. local scales at some measured input value at a suitable hypocentral distance between about 17 km (Hutton and Boore, 1987) to 100 km (Richter, 1935) (see Fig. 3.30 in Chapter 3), the teleseismic scales mB, Ms and Mw at a common average magnitude value, which is around 6.5 (Fig. 3.70 in Chapter 3; see Utsu, 2002), or the modern moment and energy magnitude scales, Me and Mw, which yield identical values at a constant ratio of released seismic energy to seismic moment (see Chapter 3, section 3.3.3 and Bormann and Di Giacomo, 2011). At other than these scaling values, however, they may differ significantly, depending on local/regional differences in wave attenuation, the difference in the periods and bandwidth at which these magnitudes are measured and/or the difference in the  $E_s/M_0$  ratio of the actual rupture process.

The required uniqueness of magnitude data can principally be assured and documented by a rather short specific magnitude names within the 5-letters ISF code, as in Table 2, yet necessitating a defining documentation in the metadata, which will – hopefully in future – also be complemented by some statistics of the authors/agencies about average absolute or mean/median and standard deviations or trend differences with respect to standard magnitudes, moment magnitudes or other magnitudes of the same type. However, **if it can be proven that agency-specific deviations in procedural details from the recommended standard procedures result in magnitude values that differ in terms of absolute average deviations not more than 0.1 m.u. from the respective standard values then they can be considered and reported as standard magnitudes as well.** Examples are given in section

3.2.3.2 of Chapter 3, in section 5 of IS 3.3 with Figure 14 and in section 5 above with the discussion in conjunction with Table 2. Guidelines with record data for such comparative measurements are given in IS 3.4 together with questionnaires for reporting the results of such a comparison as well as the agency-specific procedures for magnitude measurements to the International Seismological Center (ISC).

New procedures for magnitude measurement are continuously proposed, such as non-saturating broadband P-wave magnitude estimators which take additionally rupture duration into account [e.g., mBc by Bormann and Wylegalla (2005) and Bormann and Saul (2009); the unspecified M by Hara (2007); Mw<sub>pd</sub> by Lomax and Michelini (2009)], W-phase-based estimates of Mw and moment tensor solution estimates based on the analysis of W phases [see Kanamori and Rivera (2008), Hayes et al. (2009); Chapter 3, section 3.2.8.6] or magnitude estimates based on strong-motion data. Generally, new or modified classical procedures of magnitude determination should be clearly distinguishable from any common “generic” or standardized magnitude and be given unique specific names. Some general rules are recommended:

- If authors or institutions have given to their new magnitudes already unique names with 5 or less letters (such as mBc or Mw<sub>pd</sub>) these names should be preserved in national or international data bases, bulletins or publications in agreement with the ISF 5-letters magnitude code and links be given to relevant publications for user information;
- If such magnitudes are unspecified, then a code should be added that permits the unambiguous identification of the author, agency and type of magnitude, preferably within the ISF 5-letters restriction, e.g. MHARA or MwWPH for the W-PHase derived Mw, otherwise in an extended form as the related amplitude phase name or as accompanying metadata;
- If author/agency proposed names exceed the ISF 5-letters code one could also try to shorten it in a still comprehensible and unambiguous way, as, e.g., Ms(VMAX) was shortened into Ms\_VX in the NEIC Hydra parameter data plots;
- If possible these modifications should be agreed upon between the data centers and authors/agencies so as to assure their unique use also in publications.

## **8 The role of the ISC in implementing IASPEI standard magnitude measurements and assuring unique amplitude and magnitude nomenclature**

The WG on Magnitude measurements was set up by the IASPEI Commission on Seismic Observation and Interpretation (CoSOI) in response to a IASPEI resolution submitted in 2001 by the ISC Governing Council under the chairmanship of A. Dziewonski. Its mandate has been outlined on pages 6 and 7 above. The goals a-d have been achieved with all related documentation on the procedures, standard nomenclature, comparison with non-standard magnitudes, questionnaire on agency-specific procedures etc. being now available, including publications in peer-reviewed journals and related NMSOP-2 items [e.g., Liu et al. (2005; 2006); Bormann et al. (2007; 2009); Bormann and Saul (2008); NMSOP-2, Chapter 3, section 3.2, IS 3.3 and 3.4, DS 3.1; <http://nmsop.gfz-potsdam.de>.]

With respect to **goal a)** we can now be sure that  $mB\_BB$  is very close to the original Gutenberg (1945b) and Gutenberg and Richter (1956) body-wave magnitude  $m = mB$ , deviating in its original range of definition between  $5.5 < mB < 8.5$  less than 0.1 m.u. (see Bormann et al., 2009). The same applies when comparing  $Ms\_20$  with the classical Gutenberg (1945a)  $Ms$  and the traditional NEIC vertical component surface-wave magnitude measured around 20 s (Bormann et al., 2009; Lienkaemper, 1984).

However,  $Ms\_BB$  is the only surface-wave magnitude that agrees **perfectly** with the  $Ms$  formula proposed by Vaněk et al. (1962) which is the official IASPEI standard  $Ms$  formula since 1967. Being perfectly scaled to the original Gutenberg  $Ms$  (around 20s) that is almost exclusively based on event magnitudes  $\geq 6 - 8+$ ,  $Ms\_BB$  yields however on average for magnitudes  $3 < Ms\_20 < 6$  between 0.4 and 0.1 m.u. larger values than  $Ms\_20$ . The simple reason is that the Rayleigh wave maxima for these smaller earthquakes, which are preferentially recorded at local to regional distances, rarely occur at periods around 20 s (see Bormann et al., 2009 and Figs. 3.35 and 3.40 in Chapter 3). This also explains the systematic distance-dependent errors found by Herak and Herak (1985) and Rezapour and Pearce (1993) when  $Ms$ , calculated with the IASPEI standard formula, is based exclusively on amplitudes measured in the period range between 18 and 22s.  $Ms\_BB$  also reduces by about  $\frac{1}{2}$  the systematic bias of  $Ms\_20$  when compared with  $Mw$  for  $Mw < \approx 6.5$  (Kanamori and Anderson, 1975; Ekström and Dziewonski, 1988; Di Giacomo et al., 2013) as well as the difference between  $Ms$  with  $mb$  and  $ML$  for  $Mw < 6$  (see Chapter 3, Fig. 3.70). Since  $Ms\_BB$  may be measured down to epicentral distances of  $2^\circ$  and measured at periods as small as 3 s, it agrees in fact rather well with  $ML$  at regional distances (see Figure 5, upper right in Bormann et al., 2007, comparing  $ML$  with traditional Chinese  $Ms$  that resembles  $Ms\_BB$ ).

$ML$  (Richter, 1935, 1958),  $mb$  (Engdahl and Gunst, 1966), and  $mb(Lg)$  (Nuttli, 1973, 1985, 1986, 1988) are classical US derived magnitudes. The US members in the WG have taken care of assuring that the related new standards are compatible with these original definitions within about 0.1 m.u.

With respect to **goal b)** it has been proven by implementing the new standards both in fully automatic procedures at the NEIC, in the GFZ-GEOFON SeisComp3 real-time procedures (for  $mb$  and  $mB\_BB$ ) as well as in comprehensive off-line interactive data analyses at the China Earthquake Network Center (CENC) and at the Collm (CLL) observatory in Germany that the new standards allow to make best use of the advantages of digital data and processing. Moreover, the new broadband standard magnitudes  $mB\_BB$  and  $Ms\_BB$ , that are based on just the single measurement parameter  $V_{max}$  instead of  $A_{max}$  and  $T$ , are even more robust and have a smaller data scatter than the band-limited  $mb$  and  $Ms\_20$  (see section 3.2.3.2 in Chapter 3 and Table 5 in IS 3.3).

With respect to **goal c)** the new nomenclatures for standard magnitudes and related amplitudes are now available but have been implemented as of May 2013 only in the NEIC Hydra event data plot and in the SEISAN analysis software record plots for magnitude measurements. They are not yet available in the bulletins of the ISC, the NEIC or other agencies and stations.

Concerning **goal d)** the ISC had circulated already years ago the first versions of the IASPEI (2005) WG recommendations and of the questionnaire on current agency-specific magnitude procedures. First answers to the latter by a few stations/agencies, which had also been posted on the ISC website, revealed however some inconsistencies and ambiguities which required a

revision of the questionnaire which is now annexed to the IASPEI (2013) WG recommendations as well as to IS 3.4. This necessitates a second effort by the ISC to disseminate to all its data contributors and membership agencies these latest versions together with an urgent request for consideration, implementation and feedback in the context of outlining beforehand to them the future ISC policy in implementing these IASPEI recommendations.

Only when pioneered by the ISC as the singular true global seismological parameter data agency with the self-demand to assure - in close collaboration with IASPEI and CoSOI - the best achievable degree of data completeness, quality and unambiguity, also the other main goals e-h) can be achieved in the years ahead in the very best long-term interests of the global seismological community. This, however, also requires a majority support by the ISC Governing Council, the initiator of the IASPEI resolution and thus of the WG establishment. And this position should be independent on the particular national interests, limiting conditions or current priority tasks under which some of the ISC members or cooperating associates have to run at present their daily operations.

## Acknowledgments

The author owes great thanks to his fellow WG members for the many years of fruitful cooperation, and to J. Dewey, D. Storchak and D. Di Giacomo in particular for their critical reading the draft version of this Information Sheet. Their useful comments and editorial recommendations have helped to improve and substantiate the manuscript. J. Saul helped to clarify the representation of magnitude data in the QuakeML format.

## 1 Why there is a need for measurement standards of magnitudes

In October 2005, the Commission on Seismic Observation and Interpretation of the International Association of Seismology and Physics of the Earth's Interior (IASPEI) adopted the summary recommendations made by the IASPEI Working Group on Magnitudes on new measurement standards for widely used local, regional and teleseismic magnitude scales (IASPEI, 2005). These recommendations have recently been refined and detailed (IASPEI, 2013) and a final scientific report, to be published in a reputable international journal, is currently under preparation.

The Working Group has been established by the IASPEI General Assembly 2001 in Hanoi, following a request of the Governing Council of the International Seismological Center (ISC). The latter was concerned about significant discrepancies between short-period body-wave magnitudes  $m_b$  determined by the US Geological Survey's National Earthquake Information Center (USGS/NEIC) and the Prototype International Data Centre (PIDC), predecessor to the International Data Centre (IDC) of the Comprehensive Test-Ban Treaty Organization (CTBTO) at Vienna. Since then, significant causes of these discrepancies have been identified as coming from differences in the applied short-period filter response, in the length of the measurement time window (Granville et al., 2002 and 2005; Bormann et al., 2007 and 2009) and in the different calibration functions used (Gutenberg and Richter, 1956a, and Veith and Clawson, 1972, respectively; in the following abbreviated by G-R and V-C) for correcting the effects of epicentral distance and source depth on the measured amplitudes (Murphy and Barker, 2003; Granville et al., 2005). The average discrepancy between  $m_b$ (NEIC) and  $m_b$ (IDC) was found to be approximately +0.4 magnitude units (m.u.) (Granville et al., 2002). This difference, however, strongly increases with magnitude and is larger than 1 m.u. for really great earthquakes (e.g., 1.3 m.u. for the 2004 Mw9.3 Sumatra-Andaman earthquake; see Bormann et al., 2007). Further, the differences are smaller for shallow earthquakes than for deep earthquakes, because for source depths  $h > 300$  km the V-C corrections are on average 0.4 m.u. (up to 0.6 m.u. for the deepest earthquakes) smaller than the G-R corrections. Despite these systematic discrepancies, the USGS/NEIC and the IDC publish their body-wave magnitude with the same symbol  $m_b$ .

Similarly, the symbol  $M_s$  is commonly used both for surface-wave magnitudes based on amplitude measurements around 20 sec period and those measured in a much wider period range. For both  $M_s$  measured near 20s and  $M_s$  measured over broader period ranges, multiple attenuation functions have been proposed. These may produce magnitudes that differ systematically (sometimes up to about 0.6 m.u.), especially for smaller earthquakes recorded only at distances  $< 30^\circ$  (Bormann et al., 2009).

Publishing magnitudes derived by different measurement procedures with identical magnitude symbols may not only confuse and mislead users of such data, it also jeopardizes the authenticity, compatibility and long-term continuity of magnitude data and thus their use in earthquake statistics and related applications. For example, when merging  $m_b$ (NEIC) and  $m_b$ (IDC) data at the ISC for calculating event averages and standard deviations, systematic differences and increased data scatter may significantly bias such estimates for magnitudes larger than 5. Therefore, IASPEI realized a general need to identify such discrepancies in measurement practices of widely determined different types of magnitudes, to analyze, quantify and understand the reasons for such discrepancies and to propose international standards for making such measurements.

## 2 Aim of the proposed magnitude standards

IASPEI recommended that measurement standards for magnitudes should, as far as possible:

- agree with magnitudes of the same type that have been measured for decades from analog seismograms according to original definitions;
- promote the best possible use of the advantages of digital data and processing;
- minimize bulletin magnitude biases that result from procedure-dependent single-station or network magnitude biases;
- increase the number of seismological stations and networks with well-defined procedures;
- increase essentially the accuracy, representativeness, homogeneity and long-term global compatibility of magnitude data and their usefulness for seismic hazard assessment and research.

## 3 Summary recommendations on determining earthquake magnitudes from digital data

The Working Group on Magnitudes (for short, *Magnitude WG*) of the IASPEI Commission on Seismological Observation and Interpretation was established to recommend standard procedures for making measurements from digital data to be used in calculating several widely used types of earthquake magnitude. The recommended procedures from the *Magnitude WG* have been approved by the IASPEI Commission on Seismological Observations and Interpretations. We henceforth refer to the proposed procedures as the IASPEI standard procedures for magnitude determination. The *Magnitude WG* is planning to publish an article, in the open literature, that explains the rationale for the IASPEI standard procedures. Current members of the *Magnitude WG* are, in alphabetical order: P. Bormann (co-chair), J. M. Dewey (co-chair), I. Gabsatarova, S. Gregersen, A. Gusev, W. Kim, R. Liu, H. Patton, B. Presgrave, J. Saul, R. A. Uhrhammer, S. Wendt.

The IASPEI standard procedures address the measurement of amplitudes and periods from digital data for use in calculating the generic magnitude types  $ML$ ,  $Ms$ ,  $mb$ ,  $mB$ , and  $mb\_Lg$ . For  $Ms$ , standard procedures are proposed for two different traditions --  $Ms$  measured from waves with periods near 20s [here denoted  $Ms_{20}$ ] and  $Ms$  measured from waves in a much broader period-range [here denoted  $Ms_{BB}$ ]. For the generic intermediate-period/broadband body-wave magnitude  $mB$ , we propose a procedure based on the maximum amplitude of the  $P$ -wave measured on a velocity-proportional trace: we denote the resulting magnitude  $mB_{BB}$ . The IASPEI standard procedures also specify a standard equation for  $Mw$  from among several slightly different equations. Abbreviated descriptions of the procedures are described below. More detailed descriptions, and discussion of acceptable alternatives to specific steps in the application of individual procedures, will be discussed in the planned journal article and in the last section of this Information Sheet.

Some of the IASPEI standard procedures require the use of broadband (BB) records that are proportional to ground motion velocity at least within the period range that has been recommended for the measurement of the respective magnitudes. Other procedures require

filtering BB records so that they replicate the response of classical standard seismographs, such as the Wood-Anderson (WA) seismograph or the short-period (SP) and long-period (LP) seismographs that were used in the World-Wide Standardized Seismograph Network (WWSSN) (next section).

### 3.1 Poles and zeroes for Wood-Anderson, WWSSN-SP, and WWSSN-LP seismographs

Poles and zeroes corresponding to the displacement transfer functions for representative “average” classical analog standard seismographs WWSSN-SP, WWSSN-LP and Wood Anderson with their equivalent eigenperiod and damping of the seismometer and galvanometer and coupling factor  $\sigma^2$  (where applicable) are given in Table 1 (courtesy of Charles R. Hutt, U. S. Geological Survey, who also provided much of the immediately following documentation). Note that the number of zeroes determines the slope of the response at the low-frequency end and that this slope changes towards higher frequencies at the frequencies determined by the poles. At the frequency of a conjugate complex pole the slope is reduced by two orders, while at a single pole with real part only, the slope is reduced by one order only. The left number in brackets is the value of the real part; the right number that of the imaginary part. The normalized amplitude responses corresponding to the poles and zeroes of Table 1 are shown in Figure 1.

At magnifications of 50,000 and higher, transfer functions for the WWSSN short-period seismograph differed somewhat for different magnification settings, due to galvanometer-seismometer reaction. The response shown in Table 1 and recommended for use with *mb* is appropriate to a “100,000 magnification” short-period WWSSN seismograph.

Transfer functions for the WWSSN long-period seismograph also differed somewhat for different magnification settings, due to galvanometer-seismometer reaction. The response shown in Table 1 is appropriate to a “1500 magnification” long-period vertical WWSSN seismograph. The transfer functions of the WWSSN-LP horizontal seismograph also differed from that of the WWSSN-LP vertical seismograph. One should note that the coupling which exists in electromagnetic seismographs with galvanometric recording between the seismometer and galvanometer has been taken into account in the listed poles in such a way as to make the coupling factor effectively zero. Accordingly, the resulting free periods and damping values given for the equivalent seismometer ( $T_s$  and  $h_s$ ) and galvanometer ( $T_g$  and  $h_g$ ) in Table 1 are somewhat different from the nominal values of the uncoupled system components of classical seismographs and the respective coupling factors are reported as zero. The nominal free periods of the uncoupled components are  $T_s = 1.00$  s and  $T_g = 0.75$  s for WWSSN-SP and  $T_s = 15.0$  s and  $T_g = 100.0$  s for WWSSN-LP.

The frequency response of the Wood-Anderson seismograph (Table 1) is based on the paper of Uhrhammer and Collins (1990).

**Table 1** Zeroes and poles corresponding to the displacement transfer function of the WWSSN-SP seismograph, WWSSN-LP seismograph, and the Wood-Anderson (WA) seismograph. Zeroes and poles are represented in angular frequency (radians per second).  $T_s$  = seismometer free period;  $h_s$  = seismometer damping constant;  $T_g$  = galvanometer free period;  $h_g$  = galvanometer damping constant;  $\sigma^2$  = coupling factor. In this representation, free periods and damping constants have been adjusted slightly so that response can be correctly modeled with  $\sigma^2 = 0$ . The displacement-response functions implied by the poles and zeroes are commonly normalized with respect to the following frequencies ( $f_n$ ) using the associated normalization factors ( $A_0$ ) as follows: WWSSN-SP,  $f_n = 1$  Hz,  $A_0 = 532.14$ ; WWSSN-LP,  $f_n = 0.04$  Hz,  $A_0 = 0.97866$ ; WA,  $f_n = 4$  Hz,  $A_0 = 1.0028$ .

### 3.2 IASPEI standard procedures for widely used magnitude types

The amplitudes used in the magnitude formulas below are in most circumstances to be measured as one-half the maximum deflection of the seismogram trace, peak-to-adjacent-trough or trough-to-adjacent-peak, where peak and trough are separated by one crossing of the zero-line: the measurement is sometimes described as “one-half peak-to-peak amplitude.” None of the magnitude formulas presented in this article are intended to be used with the full peak-to-trough deflection as the amplitude. The periods are to be measured as twice the time-intervals separating the peak and adjacent-trough from which the amplitudes are measured. The amplitude-phase arrival-times are to be measured as the time of the zero-crossing between the peak and adjacent-trough from which the amplitudes are measured. The issue of amplitude and period measuring procedures, and circumstances under which alternative procedures are acceptable or preferable, is discussed further in Section 5.

Modern digital seismogram analysis programs commonly measure amplitudes in units of nm (for displacement) or nm/s (for velocity), respectively, and not, as assumed by the classical magnitude formulas, in  $\mu\text{m}$ . The commonly known classical calibration relationships have been modified to be consistent with displacements measured in nm.

***ML*** – local magnitude consistent with the magnitude of Richter (1935)

For crustal earthquakes in regions with attenuative properties similar to those of Southern California, the proposed standard equation is

$$ML = \log_{10}(A) + 1.11 \log_{10}R + 0.00189R - 2.09, \quad (1)$$

where:

$A$  = maximum **trace** amplitude in **nm** that is measured on output from a **horizontal-component** instrument that is filtered so that the response of the seismograph/filter system replicates that of a **Wood-Anderson standard seismograph** but with a static magnification of 1 (see Table 1 and Figure 1);

$R$  = **hypocentral distance in km**, typically less than 1000 km.

Equation (1) is an expansion of that of Hutton and Boore (1987). The constant term in equation (1), -2.09, is based on an experimentally determined static magnification of the Wood-Anderson of 2080, rather than the theoretical magnification of 2800 that was specified by the seismograph's manufacturer. The formulation of equation (1) reflects the intent of the *Magnitude WG* that reported *ML* amplitude data not be affected by uncertainty in the static magnification of the Wood-Anderson seismograph.

For seismographic stations containing two horizontal components, amplitudes are measured independently from each horizontal component, and each amplitude is treated as a single datum. There is no effort to measure the two observations at the same time, and there is no attempt to compute a vector average.

For crustal earthquakes in regions with attenuative properties that are **different** than those of coastal California, and for measuring magnitudes with vertical-component seismographs, the standard equation is of the form:

$$ML = \log_{10}(A) + C(R) + D, \quad (2)$$

where  $A$  and  $R$  are as defined in equation (1), except that  $A$  may be measured from a **vertical-component** instrument, and where  $C(R)$  and  $D$  have been **calibrated** to adjust for the different regional attenuation and to adjust for any systematic differences between amplitudes measured on horizontal seismographs and those measured on vertical seismographs.

***Ms\_20 – teleseismic surface-wave magnitudes at period of ~20 s***

$$Ms_{20} = \log_{10}(A/T) + 1.66\log_{10}\Delta + 0.3, \quad (3)$$

where:

$A$  = **vertical-component** ground displacement in **nm** measured from the maximum trace-amplitude of a surface-wave phase having a period between **18 s and 22 s** on a waveform that has been filtered so that the frequency response of the seismograph/filter system replicates that of a World-Wide Standardized Seismograph Network (WWSSN) **long-period seismograph** (see Table 1), with  $A$  being determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-LP response at period  $T$ ;

$T$  = period in seconds ( $18 \text{ s} \leq T \leq 22 \text{ s}$ );

$\Delta$  = **epicentral** distance in degrees,  $20^\circ \leq \Delta \leq 160^\circ$ ;

Equation (3) is formally equivalent to the  $Ms$  equation proposed by Vaněk et al. (1962) but is here applied to vertical motion measurements in a narrow range of periods.

Some agencies compute  $Ms_{20}$  only for shallow-focus earthquakes (typically those whose confidence-intervals on focal-depth would allow them to be shallower than 50 or 60 km).  $Ms_{20}$  would be expected to significantly under-represent the energy of intermediate- and deep-focus earthquakes, due to their less effective generation of surface waves, unless an adjustment is made to account for their large focal-depths, e.g., according to Herak et al. (2001).

***Ms\_BB – surface-wave magnitudes from broad-band instruments***

$$Ms_{BB} = \log_{10}(V_{max}/2\pi) + 1.66 \log_{10}\Delta + 0.3, \quad (4)$$

where:

$V_{max}$  = ground **velocity in nm/s** associated with the maximum trace-amplitude in the surface-wave train, as recorded on a **vertical-component** seismogram that is **proportional to velocity**, where the period of the surface-wave,  $T$ , should satisfy the condition  $3 \text{ s} < T < 60 \text{ s}$ , and where  $T$  should be preserved together with  $V_{max}$  in bulletin data-bases;

$\Delta$  = **epicentral** distance in degrees,  $2^\circ \leq \Delta \leq 160^\circ$

As with  $M_s_{20}$ , some agencies compute  $M_s_{BB}$  only for shallow-focus earthquakes.

Equation (4) is based on the  $M_s$  equation proposed by Vaněk et al. (1962), but is here applied to vertical motion measurements and is used with the  $\log_{10}(V_{max}/2\pi)$  term replacing the  $\log_{10}(A/T)_{max}$  term of the original.

***mb*** – short-period body-wave magnitude

$$mb = \log_{10}(A/T) + Q(\Delta, h) - 3.0, \quad (5)$$

where:

$A$  = P-wave ground amplitude in **nm** calculated from the maximum trace-amplitude in the **entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, and ending preferably before PP);

$T$  = period in seconds,  $T < 3 \text{ s}$ ; of the maximum P-wave trace amplitude.

$Q(\Delta, h)$  = attenuation function for **PZ** (P-waves recorded on vertical component seismographs) established by **Gutenberg and Richter (1956a)** in the tabulated or algorithmic form as used by the U.S. Geological Survey/National Earthquake Information Center (USGS/NEIC) (**Table 2**);

$\Delta$  = **epicentral** distance in degrees,  $20^\circ \leq \Delta \leq 100^\circ$ ;

$h$  = focal depth in **km**;

and where both  $T$  and the maximum trace amplitude are measured on output from a **vertical-component** instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a WWSSN **short-period** seismograph (**Table 1**), with  $A$  being determined by dividing the maximum trace amplitude by the magnification of the simulated WWSSN-SP response at period  $T$ .

***mB\_BB*** – broadband body-wave magnitude

$$mB_{BB} = \log_{10}(V_{max}/2\pi) + Q(\Delta, h) - 3.0, \quad (6)$$

where:

$V_{max}$  = ground **velocity in nm/s** associated with the maximum trace-amplitude in **the entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, but ending *preferably* before PP (*Note: see discussion in the final section*), as recorded on a vertical-component seismogram that is **proportional to velocity**, where the period of the measured phase,  $T$ , should satisfy the condition  $0.2 \text{ s} < T < 30 \text{ s}$ , and where  $T$  should be preserved together with  $V_{max}$  in bulletin data-bases;

$Q(\Delta, h)$  = attenuation function for PZ established by Gutenberg and Richter (1956a), (Table 2);

$\Delta$  = epicentral distance in degrees,  $20^\circ \leq \Delta \leq 100^\circ$ ;

$h$  = focal depth in **km**.

Equation (6) differs from the equation for  $m_B$  of Gutenberg and Richter (1956a) by virtue of the  $\log_{10}(V_{max}/2\pi)$  term, which replaces the classical  $\log_{10}(A/T)_{max}$  term.

**Table 2** Attenuation (Q) function to be used with  $mb$  (equation 5) and  $mB_{BB}$  (equation 6). This version of  $Q(\Delta, \text{focal-depth})$  was digitized in the 1960's from Figure 5 of Gutenberg and Richter (1956a) and is used at the USGS/NEIC. This is a comma-delimited file, intended to be copied into applications, with the first two rows being header rows. The first column is epicentral distance  $D (= \Delta)$  in degrees, and the following columns give Q for distance  $D$  and depths 0, 25, ...700 km. For  $D$  and focal-depth lying between tabulated values, Q is obtained by linear interpolation from the four neighboring tabulated values.

***mb\_Lg*** – regional magnitude based on the amplitude of *Lg* measured in a narrow period range around 1 s

$$mb\_Lg = \log_{10}(A) + 0.833\log_{10}[r] + 0.4343\gamma(r - 10) - 0.87 \quad (7)$$

where:

*A* = “sustained ground-motion amplitude” in **nm**, defined as the third largest amplitude in the time window corresponding to group velocities of 3.6 to 3.2 km/s, in the period (*T*) range 0.7 s to 1.3 s;

*r* = **epicentral distance** in **km**

$\gamma$  = coefficient of attenuation in  $\text{km}^{-1}$ .  $\gamma$  is related to the quality factor *Q* through the equation  $\gamma = \pi/(Q \cdot U \cdot T)$ , where *U* is group velocity and *T* is the wave period of the *Lg* wave.  $\gamma$  is a strong function of crustal structure and should be determined specifically for the region in which the *mb\_Lg* is to be used.

*A* and *T* are measured on output from a **vertical-component** instrument that is filtered so that the frequency response of the seismograph/filter system replicates that of a WWSSN **short-period** seismograph. Arrival times with respect to the origin of the seismic disturbance are used, along with epicentral distance, to compute group velocity *U*.

***Mw*** – moment magnitude

$$Mw = (\log_{10}M_0 - 9.1)/1.5,$$

where *M<sub>0</sub>* = scalar moment in **N·m**, determined from waveform modeling or from the long-period asymptote of spectra.

or its CGS equivalent (*M<sub>0</sub>* in **dyne·cm**),

$$Mw = (\log_{10}M_0 - 16.1)/1.5.$$

The order of operations in the right-hand sides of equations for *Mw*, subtraction prior to multiplication by 2/3, avoids an ambiguity that arises if multiplication is performed prior to subtraction, which in a certain percentage of cases leads to *Mw* being different according to whether the moment is expressed in CGS or SI units (Utsu, 2002). In this context it may be worth mentioning, that P. Bormann and G. Choy have agreed on the same way of standardized writing of the energy magnitude relationship  $Me = (\log E_S - 4.4)/1.5$  instead of the expanded and rounded-off version  $Me = (2/3)\log E_S - 2.9$ .

### 3.3 Magnitude nomenclature

The “*ML*, *Ms\_20*, *Ms\_BB*, *mb*, *mB\_BB*, *Mw*, *mb\_Lg*” nomenclature used in this section of IS\_3.3 is defined to facilitate data transmission in the IASPEI Seismic Format (ISF) (International Seismological Centre, <http://www.isc.ac.uk/standards/isf>, last accessed March

2012). In the ISF format, magnitude nomenclature is restricted to five characters. The recommended magnitude nomenclature is intended to be consistent with nomenclature that has been used by editorial boards of the Bulletin of the Seismological Society of America, except that the recommended nomenclature does not subscript characters and uses a hyphen in place of parentheses in order to reduce character count. The representation of the magnitude names in italics is for the purpose of distinguishing nomenclature from regular text in the present section of this Information Sheet; we do not consider italics an element of nomenclature. The recommended nomenclature differs from other widely used current nomenclatures. Relationships between nomenclatures are illustrated in Table 3.

In Table 3 “**BSSA editorial style**” is the nomenclature that seems to us most representative of style recommended in recent decades by editors of the Bulletin of the Seismological Society of America. “**NMSOP generic**” and “**NMSOP specific**” are respectively the “generic” and “specific” nomenclature used in the first edition of the IASPEI New Manual of Seismological Observatory Practice (Bormann, 2002a, 2002b). In the specific nomenclature the general magnitude symbol *M* is followed by the symbol of the seismic phase and then by the symbol of the component (V – vertical; H – horizontal) on which amplitude is measured. Then the first letter(s) in brackets stand(s) for the instrument type on which magnitude is measured: e.g., A = WWSSN-SP, B = WWSSN-LP, D = velocity broadband, WA = Wood Anderson. Further symbols/names stand for specific calibration functions used, e.g., “CF” for California and “Author” for author- or agency specific calibration function. “USGS Search” is the nomenclature used by the USGS/NEIC in its Earthquake Catalog Search (<http://neic.usgs.gov/neis/epic/>, last accessed March 2012). “USGS EDR” is the nomenclature used by the USGS/NEIC in its on-line machine-readable Earthquake Data Reports (<ftp://hazards.cr.usgs.gov/edr/>, last accessed March 2012). “ISC” is the nomenclature historically used by the International Seismological Centre. USGS/NEIC and ISC nomenclature has changed as advances in information technology have permitted greater flexibility in nomenclature.

**Table 3** A sample of alternative nomenclatures for the magnitude types that are considered in this report. For detailed explanation see text.

| This report | BSSA editorial style                   | NMSOP generic | NMSOP specific          | USGS Search | USGS EDR | ISC                  |
|-------------|----------------------------------------|---------------|-------------------------|-------------|----------|----------------------|
| ML          | <i>M<sub>L</sub></i>                   | Ml            | MH(WA;CF),<br>MV(WA;CF) | ML          | ML       | <i>M<sub>L</sub></i> |
| Ms_20       | <i>M<sub>S</sub></i> (20)              | Ms            | MLV(B)                  | Ms          | MSZ      | Ms                   |
| Ms_BB       | <i>M<sub>S</sub></i> (BB)              | Ms            | MLV(D)                  | --          | --       | Ms                   |
| mb          | <i>m<sub>b</sub></i>                   | mb            | MPV(A)                  | mb          | MB       | Mb                   |
| mB_BB       | <i>m<sub>B</sub></i> (BB)              | mB            | MPV(D)                  | --          | --       | mB                   |
| mb_Lg       | <i>m<sub>b</sub></i> (L <sub>g</sub> ) | mbLg          | MLgV(A;Author)          | Lg          | LG       | MN                   |

In conjunction with the full-fledged implementation of the new IASPEI standards, the WG encourages seismological agencies to work toward harmonizing their nomenclatures in order

to minimize misunderstanding on the side of data users and to better guide users' search for standard magnitude data.

### 3.4 Nomenclature for amplitudes, periods, and amplitude-measurement times

The ISF (IASPEI Seismic Format) data-exchange format that was discussed in the previous section allows for data lines (the ARRIVAL data type) to convey station-specific magnitude data. The amplitude, period, and amplitude-measurement time that is associated with a single magnitude measurement is transmitted on a single line, along with the calculated station-magnitude value. A “phase name” (see **Table 4**) must generally be associated with the data.

**Table 4** ISF “phase names” to be used for transmittal of amplitudes, periods, and amplitude-measurement times for the standard magnitude types considered in this paper. “I” stands for “International” or “IASPEI”, “A” for displacement amplitude, and “V” for velocity amplitude.

| Magnitude type | Phase Name |
|----------------|------------|
| ML             | IAML       |
| Ms_20          | IAMs_20    |
| Ms_BB          | IVMs_BB    |
| mb             | IAmb       |
| mB_BB          | IVmB_BB    |
| mb_Lg          | IAmb_Lg    |

### 3.5 Agency-specific circumstances that may lead to modification of standard procedures

The IASPEI Standard Procedures are proposed for implementation by seismological agencies in general. Adoption of the Standard Procedures by an agency will make that agency's magnitudes more useful to global seismological research and will enable the agency to directly compare its own results with IASPEI standard magnitudes produced by other agencies. The *Magnitude WG* recognizes, however, that agency-specific circumstances may make it desirable for individual agencies to use procedures that differ from the Standard Procedures. In this case, agency documentation and agency-produced bulletins should contain sufficient information to allow a user to understand how the agency's magnitudes can be related to magnitudes produced by the Standard Procedures.

For situations in which data demand modifications to the attenuation equations that are specified in the Standard Procedures, we recommend the practice that has been followed in the historic development of magnitude scales: the current standard equations are to be used as baselines for defining otherwise arbitrary constants in the improved equations. An agency

magnitude-type that is commonly, or in certain magnitude ranges, biased by more than 0.1 magnitude unit with respect to the magnitude produced by an IASPEI Standard Procedure should be identified by nomenclature that is distinct from the IASPEI magnitude nomenclature.

**Note:** The preceding material of this section (3) was reproduced with minor modification from IASPEI (2013). A following subsection in IASPEI (2011 and 2013), entitled “**DOCUMENT-ATION OF STATION/AGENCY MAGNITUDE PROCEDURES,**” has been attached in NMSOP-2 as Annex 2 to IS 3.4 “Guidelines for using the IASPEI standard magnitude reference data set”. This permits seismic stations/agencies to respond to this questionnaire in conjunction with the invitation to analyze the standard magnitude reference data set. In fact, this is the first practical step to educate and train station/agency personnel in the application of the IASPEI standard procedures in comparison with their traditional practices of magnitude determination.

#### **4 Relation of IASPEI standard procedures to original magnitude definition and to procedures for measuring magnitudes at different agencies**

As summarized in section 2, the IASPEI recommended measurement standards should, as far as possible, produce magnitudes that are consistent with magnitudes of the same type that have been measured for decades from analog seismograms according to original definitions. This aims at assuring continuity of magnitude estimates published in older and younger earthquake catalogs. We outline below to what extent this has been achieved or, if not, what are the reasons and advantages for deviations.

##### **4.1 ML**

The local magnitude scale was developed by Richter (1935) for earthquakes in Southern California. The tabulated calibration values according to Richter (1958) are presented in DS 3.1. The more recent Hutton and Boore (1987) formula for Southern California, on which the standard ML(IASPEI) formula (1) is based, agrees well for hypocentral distances  $R$  between  $50 \text{ km} < R < 200 \text{ km}$  with the Richter calibration values, but produces higher values (up to 0.6 m.u.) for nearby stations ( $R < 50 \text{ km}$ ;) and lower (up to 0.24 m.u.) values for more distant stations up to 600 km (see also Fig. 3.30 in Chapter 3). The large effect at close distances is due to the fact that (according to Hutton and Boore) Richter assumed a geometric spreading with  $1/r^2$  whereas the observed spreading is  $\approx 1/r$ .

However, ML(IASPEI) differs from the Hutton and Boore (1987) ML by accounting for the difference in static magnification assumed by the manufacturer of the WA instruments (2800) and the one empirically determined by Uhrhammer and Collins (1990), which is about 2080. If ML(H-B) is measured on an original WA record then this difference does not matter. However, when compared with ML(H-B) on a WA simulation record one would expect ML(IASPEI) to be larger than ML(H-B) by  $\log(2800/2080) = 0.13 \text{ m.u.} = \text{constant}$ . Both effects together (i.e., the use of the Hutton and Boore calibration function and the correction for a constant difference in static magnifications) would produce in the epicentral distance range  $0 \text{ km} < D \leq 600 \text{ km}$  differences between ML(Richter 1935 synthesized) and ML(IASPEI) as depicted in Figure 2.

**Figure 2** Difference between ML(1935) and ML(IASPEI) as a function of epicentral distance when using, for ML(1935), the Richter (1958) tabulated calibration values (therefore the saw-tooth-pattern in the above figure) and **simulated** WA records assuming a static magnification of 2800 and, for ML(IASPEI), the calibration formula (1) with amplitudes measured on simulated WA records assuming a constant, empirically determined average static magnification of 2080 by Uhrhammer and Collins (1990). This accounts for a constant difference between these two magnitude values of  $\log(2800/2080) = 0.13$  m.u. (courtesy of K. Stammler, Federal Institute for Geosciences and Natural Resources, BGR, 2012).

However, as pointed out already by Kim (1998), the difference between the old and the empirically determined WA response **is not constant, but frequency-dependent and on average for frequencies at which ML is typically measured, about 0.1 m.u., i.e., 0.03 m.u. less than assumed in Figure 2**. According to D. Bindi (2011, personal communication) the difference varies from 0.065 m.u. at the WA eigenperiod of 0.8 s to 0.13 m.u. at about 8 times longer and shorter periods, respectively, because the damping parameter of the recalibrated WA is not 0.8 (as originally assumed) but 0.7 (see Table 1). For more details see *Comment 1.1* in DS 3.1.

#### 4.2 mB (mB\_BB)

mB is the original Gutenberg (1945b and c) body-wave magnitude. It was measured on relatively broadband medium-period instruments at periods between 2 s and 20 s (mostly between 5 s and 10 s) (see Abe and Kanamori 1980; Abe 1981 and 1984). The IASPEI recommendation to measure the maximum amplitude within the whole P-wave train, including also depth phases of P, follows the practice of Gutenberg. Gutenberg and Richter (1956a) published calibration functions for vertical and horizontal component amplitudes of P and PP waves as well as for horizontal component amplitudes of S waves amplitudes. The IASPEI standard uses only vertical component P-wave readings. For this reason, and to

reflect other modifications discussed in the following paragraphs, the IASPEI standard nomenclature is specified as  $mB_{BB}$ .

Gutenberg measured the vast majority of  $mB$  for earthquakes with magnitudes larger than 6.5. With current velocity BB instruments of high dynamic range it is possible to determine  $mB_{BB}$  down to about magnitude 4 (at best) or 5 (see Bormann et al. 2007 and 2009). The current instruments also permit reliable measurements to be made at periods above 20s. The new standards have therefore broadened the period range within which  $mB_{BB}$  may be measured beyond the earlier *de facto* range, to  $0.2 \text{ s} < T < 30 \text{ s}$ .

The other change is that Gutenberg measured the  $(A/T)_{\max}$  on displacement records. The standard, however, recommends to measure  $V_{\max}$  on velocity broadband records instead and use  $(V_{\max}/2\pi)$  as a proxy for  $(A/T)_{\max}$ . As a matter of fact, analysts tend to measure on displacement records  $A_{\max}/T$  instead of  $(A/T)_{\max}$ , yet the former often occurs at longer periods with the tendency to underestimate  $(A/T)_{\max}$  and thus  $mB$ , especially for smaller earthquakes. This has been confirmed by comparing traditional measurements of  $mB$  and related  $T$  at the Chinese Earthquake Network Center (CENC), based on Kirnos-type of displacement broadband records, with  $mB(BB)$  and related  $T$  measured on velocity broadband records. Despite these differences in old and new measurement practice the agreement between  $mB(\text{CENC})$  and  $mB_{BB}$  is on average 1:1 for magnitudes above 6 (the Gutenberg magnitude range); around  $mB_{BB} = 5$ , however, the classical  $mB(\text{CENC})$  is about 0.2 m.u. lower (see related Figures Chapter 3 or in Bormann et al., 2009).

In summary: Standard  $mB_{BB}$  agrees for values  $> 6.0$  well with Gutenberg's  $mB$  measured on displacement-proportional medium-period instruments. However,  $mB_{BB}$  is applicable in a wider range of periods and magnitudes than was usually used with traditional  $mB$ , is measured directly from  $V_{\max}$ , and is thus more closely and with less scatter related to released seismic energy than the traditional  $mB$ .

Therefore, routine measurement of broadband  $mB_{BB}$  should become a must in future, at least for earthquakes with magnitudes above 5.5. Although no knowledge of period is required for calculating  $mB_{BB}$  it should be measured and reported, because the period at which  $V_{\max}$  is observed is, on average, closely related to the corner period of the radiated source spectrum, increases with magnitude and decreases with increasing stress-drop and rupture velocity (see Chapter 3). While for smaller earthquakes recorded with low SNR in broadband records the measured periods may be strongly biased by the periods of dominating microseismic noise, Figure 3 reveals for magnitudes above 6 the expected exponential increase of period with magnitude.

### 4.3 mb

$mb$  was introduced into global observatory practice with the rapid increase in the number of sensitive short-period seismographs associated with the deployment of the World-wide Standard Seismograph Network (WWSSN), with the installation of arrays of short-period seismographs, and with regional deployments of short-period (SP) seismographs. They were mostly of the type of the WWSSN-SP response, of the later follow-up PDE-response used at the USGS/NEIC, the response used at the International Data Center (IDC, former Preliminary IDC = PIDC) of the CTBTO (see Figure 3) or covering the SP frequency range between about 1 Hz and 4 Hz in a similar way with relative bandwidth of only one to two octaves.

**Figure 3** Normalized displacement responses of a typical WWSSN short-period seismograph, of the band-pass filtered record output used by the USGS prior to 2009 for its automatic PDE processing procedure, and the filter response according to the PIDC (now IDC) procedure for short-period data analysis. All responses are normalized to have the same peak gain (modified to same abscissa-ordinate scaling as in Figure 1 from Granville et al., 2005, p. 1813, Fig. 4, © Seismological Society of America).

The high sensitivity of such band-limited short-period seismographs at quiet sites allowed for a dramatic lowering of the size threshold for which teleseismic body-wave magnitudes could be assigned. On the other hand it became clear that for strong earthquakes, mb measurements tend to be systematically less than other types of magnitude, and the effect is dramatic (more than 1 m.u.) for great earthquakes (e.g., Figure 4 in Kanamori, 1983). This effect is sometimes termed “magnitude saturation” (more correctly, a relative insensitivity to increase in the moment of the earthquake). It has two components, a spectral and a rupture-duration related one. Spectral “saturation” begins when the corner frequency of the radiated seismic source spectrum (e.g., Aki, 1967; Geller, 1976; Bormann et al., 2009; and Chapter 3), respectively of the recorded input wave spectrum, is lower than the corner frequency of the seismometer response. With reference to mb and Figure 3 this means that “saturation” is expected to begin earliest for mb(IDC) and latest for mb(WWSSN-SP). Yet mB\_BB, measured for periods up to 30 s, saturates accordingly much later than any mb. However, the IDC response allows to measure mb still reliably for smaller events than one can measure on WWSSN-SP records, because of its steeper roll-off and thus improved SNR towards lower frequencies and its peak magnification at 2 times higher frequency.

These comparisons give a feeling for the average influence of different SP seismometer responses on mb magnitude estimates. For the cases investigated they are significant ( $> 0.1$  m.u.) for the PIDC = IDC response. Another case will be discussed in section 5.1.2.

Yet, besides differences in seismograph responses used at different agencies and related differences in spectral “saturation” the application of different measurement time-window after the P-wave first onset may become even the dominating factor on the measured mb values. This is surely the case when the rupture duration of earthquakes and especially the time after the P onset at which the largest spectral amplitudes are released significantly exceed the measurement time-window within which  $(A/T)$  is measured. Bormann et al. (2009) derived a simple formula for calculating the average rupture duration  $T_R$  in its dependence on the largest event magnitude  $M$ :  **$\log T_R = 0.6M - 2.8$** . For individual earthquakes, however, the rupture duration may be up to about 2-3 times longer or shorter than estimated by this simple formula, due to differences in stress drop and rupture velocity.

In the first years of the WWSSN the United States Coast and Geodetic Survey (USCGS) instructed data analysts to measure  $A_{\max}$  in the P-wave train within the first 5 half-cycles. Somewhat later this was extended to within the first 5 s after the P-wave onset. The latter practice is still kept by the IDC of the CTBTO (5.5 s after the first P-onset; see Chapter 17). The reason for this time-window setting was that the WWSSN had as one of its main goals not only the best possible detectability of weak events but also the discrimination between natural earthquakes and underground nuclear explosions. And this discrimination capability was enhanced by measuring within such a short early P-wave time-window, within which explosions surely release their maximum of energy. This, however, is usually not the case for earthquakes with magnitudes larger than 6 for which rupture durations - on average - last for more than 6 s. This, probably, led the IASPEI Commission on Practice to propose in its first report of 1972 to extend the measurement time window for P-wave amplitudes to “15 or 25 s”.

Yet at some stations routine practice prior to 1972 was to always measure the maximum amplitude within the whole P-wave train. The first author, for example, introduced this practice at the seismological observatory Moxa (MOX), Germany, in 1965. Figure 4 shows a record example from 1965 (Bormann, 1969) and Tab. 3.1 of Chapter 3 gives a data example from the bulletin 1967 (Bormann and Stelzner, 1972).

**Figure 4** Displacement records of a 1965 Aleutian Islands earthquake at station MOX, Germany. **Below:** Records of type A (SP; 4 octave bandwidth); **Above:** Record of type B (medium period; 8 octave bandwidth). Note the multiple rupture process with  $P_{\max}$  arriving only 40 s after P1.  $mb1 = 5.8$  and  $mb4 = 7.0$  as compared to  $mB1 = 6.4$  and  $mB4 = 7.9$ . When compared with  $mB1$  and  $mB4$ , the spectral underestimation for the more short-period  $mb1$  is  $-0.6$  m.u., for the more long-period  $mb4 = -0.9$  m.u. (Bormann, 1969).

The main difference between the traditional Moxa practice and the currently proposed IASPEI  $mb$  procedure was that instead of the WWSSN-SP response the Moxa procedure used a more broadband SP type A record, displacement-proportional between 0.8 and 10 Hz. Additionally, in the case of a multiple rupture process, for all major subsequent P onsets, from the initial one up to  $P_{\max}$ , the amplitudes, periods and related magnitudes were measured both in the SP and medium-period (Kirnos SKD) records.

Experience thus collected led Bormann and Khalturin (1975) to state: „...that the extension of **the time interval for the measurement of (A/T)<sub>max</sub> up to 15 or 25 sec., ... is not sufficient** in all practical cases, **especially not for the strongest earthquakes...**” and to recommend in such cases an extension of the measurement to at least 1 min after the first P onset. This recommendation was accepted at the IASPEI meeting in 1976 and included in the Willmore (1979) edition of the Manual of Seismological Observatory Practice. This became also common practice at the USGS/NEIC. Yet, a few extraordinarily large earthquakes confirmed that the rupture duration may last even for several minutes and P<sub>max</sub> arrive even well after 60 s (see record examples in Bormann and Saul, 2008; 2009a). Therefore, Houston and Kanamori (1986) proposed to measure m<sub>b</sub> from the maximum amplitude over the whole P waveform recorded on WWSSN-SP records, without setting a fixed time-window limit, as now recommended by the new IASPEI standard.

A consequence of the different practices of m<sub>b</sub> measurement, both with respect to the frequency responses and measurement time windows used, has been rather different correlation relationships between m<sub>b</sub> and M<sub>s</sub> (see Chapter 3, section “Relationships between magnitude scales”) as well as between the m<sub>b</sub> values of different agencies. Bormann et al. (2007; Figure 2, courtesy of S. Wendt, 2003) showed that the difference between m<sub>b</sub>(PDE) and m<sub>b</sub>(PIDC) is on average +0.06 m.u. for m<sub>b</sub>(PDE) < 4.0, +0.38 m.u. for m<sub>b</sub>(PDE) between 4.0-4.9, +0.48 m.u. for m<sub>b</sub>(PDE) between 5.0-5.9 and 0.61 for m<sub>b</sub>(PDE) > 5.9, and that it reached +1.5 m.u. for the great Mw9.3 Sumatra 2004 earthquake with m<sub>b</sub>(PDE) = 7.2. The IASPEI (2005) recommended m<sub>b</sub> procedure yielded m<sub>b</sub> = 7.5 (Bormann et al., 2007) and thus a difference with respect to m<sub>b</sub>(IDC) of 1.8 m.u.

In contrast, the difference between m<sub>b</sub>(PDE), measured by the USGS prior to 2009 with the response shown in Figure 3, and the m<sub>b</sub>(IASPEI\_CENC) is much less, where CENC stands for China Earthquake Network Center, which tested extensively the application of the IASPEI standard procedures for magnitude measurement. According to Bormann et al. (2009) the orthogonal regression relationship is

$$m_b(\text{PDE}) = 0.90 m_b(\text{IASPEI\_CENC}) + 0.59. \quad (8)$$

Relationship (8) yields average differences, m<sub>b</sub>(PDE) – m<sub>b</sub>(IASPEI\_CENC), between +0.14 m.u. and -0.11 m.u. for m<sub>b</sub>(IASPEI\_CENC) between 4.5 and 7.0, but differences may reach 0.5 m.u. for still larger m<sub>b</sub> values because of the 60 s limit of the old USGS m<sub>b</sub> measurement time-window.

In summary: since standard m<sub>b</sub> is measured on simulated records with the same frequency response as early WWSSN records, a significant spectral saturation effect for larger magnitudes remains. However, by measuring A<sub>max</sub> in a variable, rupture-duration dependent measurement time-window, the further reduction of m<sub>b</sub> by using a too short fixed time-window is now avoided. Thus, as shown by Houston and Kanamori (1986) and Bormann et al. (2009), m<sub>b</sub> values up to about 7.5 can now be measured, giving a more realistic picture of the high-frequency energy release and thus the shaking potential of great earthquakes. For earthquakes with magnitudes below 5-6, however, routine measurement time-windows within the first 5 to 10 s after the P-wave introduce, as a rule, no significant bias. Slight differences of actual WWSSN-SP responses and related simulation filters from the adopted standard may result in average m<sub>b</sub> differences of about 0.03 m.u. (see, e.g., Figure 11) or, when rounded to the nearest 0.1 m.u., in rounding differences of maximum 0.1 m.u. for about 30% of the events.

#### 4.4 Ms\_20

Ms\_20 replicates the procedure by which Ms(PDE) has been computed for almost four decades by the USGS/NEIC. Ms\_20 is supposed to be closest to the original definition of the surface-wave magnitude by Gutenberg (1945a). This is empirically true yet requires some clarification about significant differences in measurement procedures and applied calibration function. Gutenberg's Ms formula reads, when A is measured in  $\mu\text{m}$ :

$$M_s = \log A + 1.656 \log \Delta + 1.818. \quad (9)$$

It is applicable between  $20^\circ \leq \Delta < 130^\circ$  with differences  $< 0.05$  m.u. as compared to respective tabulated values in Gutenberg (1945a) (see also DS 3.1 of this Manual). The latter, however, account better than the simple formula for the energy focusing of surface waves towards the antipodes. The differences between Ms values calculated for larger distances according to (9) or by using the tabulated calibration values are 0.07 m.u. at  $140^\circ$ , 0.12 m.u. at  $160^\circ$  and 0.55 m.u. at  $180^\circ$ .

Note, that formula (9) uses only displacement amplitudes A. Gutenberg himself did not note in his notebooks, at which period A had been measured, because he had defined his Ms scale for “periods of about 20 s”. As a matter of fact, surface-wave maxima in records of earthquakes with magnitudes  $> 7$  and those with dominatingly oceanic travel paths tend to have periods around 20 s. This was the case for most of the records analyzed at Pasadena in these early years. Moreover, Gutenberg (1945a) and Gutenberg and Richter (1956b) argued that a measurement period of about 20s, in preference to significantly shorter periods, would for earthquakes of focal-depth less than 40 km suppress significant underestimation of Ms that might result from strong depth-dependence of surface-wave excitation at the shorter periods. Yet, comparison with the original bulletins also of other stations used by Gutenberg as data sources for calculating the Gutenberg-Richter  $M_{GR}$  magnitudes in “Seismicity of the Earth” (Gutenberg and Richter, 1954) showed that periods as low as 12 s and as high as 23 s were sometimes used, with values outside of the period range 18 s to 22 s not being rare (Abe, 1981; Lienkaemper, 1984).

Further, the Gutenberg formula was derived for scaling horizontal component surface-wave readings, but Gutenberg did not determine the true maximum vector sum of the surface-wave amplitudes in the N-S and E-W component measured at the same time (or within  $1/4^{\text{th}}$  to  $1/2^{\text{th}}$  of the measured period, as commonly practiced or assumed). Rather, Gutenberg “vectorially” combined the largest surface-wave amplitudes measured in the two horizontal components although they may arrive at rather different times and belong to different types of surface waves. This may, in the extreme, result in 0.15 m.u. too large magnitude estimates, if both Rayleigh (LR) and Love waves (LQ) have comparably large amplitudes and the backazimuth of wave approach is  $0^\circ + n90^\circ$  with  $n = 0, 1, 2$ , or 3. An example is shown in Figure 5.

The U.S. Coast and Geodetic Survey, predecessor to the USGS/NEIC, began publishing Ms\_20 values in 1968. The U.S. agency formalized the Gutenberg tendency to prefer waves with periods near 20s (the USGS/NEIC uses periods in the 18s – 22s range) but adopted an IASPEI recommendation that the magnitude formula be that of Vaněk et al. (1962)

$$M_s = \log_{10}(A/T)_{\text{max}} + 1.66 \log \Delta + 3.3, \quad (A \text{ in } \mu\text{m}). \quad (10)$$

**Figure 5** The difference between  $M_s$  derived from these records according to the Gutenberg “vectorial” combination  $A_{Hmax} = (LR_E^2 + LQ_N^2)^{1/2}$  and the true  $A_{Hmax}$  of LR is +0.12 m.u. This is about the largest difference possible (0.15 m.u.) and depends on the BAZ (here  $85^\circ$ ).

The U.S. agency procedure also suggested that contributing observatories measure horizontal component surface-wave amplitudes measured at simultaneous arrivals (Lienkaemper, 1984), thus allowing to calculate the true vectorial  $A_{Hmax}$ . The latter change, together with some other factors explained by Lienkaemper (1984), makes  $M_{s\_20}$  empirically compatible with the classical Gutenberg-Richter (1954) magnitudes in “Seismicity of the Earth”. This is confirmed by Figure 6. For more detailed discussion see Chapter 3.

**Figure 6** Comparison of  $M_s$ (Gutenberg, 1945a) and  $M_{s\_20}$ (IASPEI) when vectorially combining for the former the largest N-S and E-W component amplitude readings and for the latter the largest radial (R) surface-wave component amplitude (courtesy of S. Wendt, 2011).

The introduction of stable long-period vertical component (V) seismometers into global seismological practice in the 1960s introduced another change in  $M_s$  measurement. According to Hunter (1972) the differences between  $M_s(V)$  and  $M_s(H)$  are negligible, as confirmed by Bormann and Wylegalla (1975). According to their orthogonal regression relationship

$$MLV = 0.97MLH + 0.19, \quad (11)$$

the two magnitudes differ on average in the range from 4 to 8.5 less than 0.07 m.u.

From May 1975 onwards, the USGS decided to calculate their  $M_s$  exclusively from vertical component readings. Since that time,  $M_s(\text{NEIC})$  is in fact identical with the IASPEI confirmed standard magnitude  $M_{s\_20}$ .

An important feature of the IASPEI  $M_{s\_20}$  formula, equation (3), is that the original formula (10) was derived using data collected over a broader distance range and over a much broader range of periods than the ranges to which the formula is restricted in equation (3). A number of studies, cited in 5.3.3, have suggested that the restriction of equation (3) to periods near 20s produces a distance-dependent bias within the  $20^\circ$  --  $160^\circ$  distance range to which equation (3) is restricted by the  $M_{s\_20}$  formula. Alternative formulas have been proposed to reduce this bias and to allow extension of the  $M_{s\_20}$  procedure to distances less than  $20^\circ$ .

$M_s$  based on surface waves near 20s are computed by the CTBTO/IDC with an alternative formula (equation 18 of Rezapour and Pearce, 1998) in place of the IASPEI formula, and using data from distances  $2^\circ$  --  $100^\circ$ , instead of  $20^\circ$  --  $160^\circ$  (Stevens and McLaughlin, 2001). The  $M_{s\_20}(\text{IDC})$  values are published with some delay in the online bulletin of the ISC (International Seismological Centre, <http://www.isc.ac.uk/iscbulletin/search/bulletin/>, last accessed March 2012). The IDC computes  $M_{s\_20}(\text{IDC})$  for nearly an order of magnitude more events than the USGS/NEIC. For events in common, the  $M_{s\_20}(\text{IDC})$  values tend to be about 0.1 magnitude units smaller than  $M_{s\_20}$  produced by the USGS/NEIC, although for stations in common the amplitudes computed at the IDC and USGS/NEIC agree to within several hundredths of a magnitude unit on average (Stevens and McLaughlin, 2001).

#### 4.5 $M_{s\_BB}$

Besides the U.S. preferred practice for calculating  $M_{s\_20}$ , there has long existed another tradition of  $M_s$  determination in a much wider range of periods between about 2 and 25 s. Even in pre-WWII bulletins of many stations world-wide that were equipped with classical mechanical or electromagnetic medium-period broadband seismographs of Wiechert, Mainka, Bosch-Omori, Galitzin, or similar, one regularly finds readings of surface-wave maxima at periods outside the range of 18-22 s. Since the 1950s, first-rate stations deployed all over the former Soviet Union (FSU) territory and later also in most FSU allied countries of Eastern Europe, as well as those in Mongolia, China, and Cuba have been equipped with displacement proportional broadband seismographs of type Kirnos. The earlier version (SK) had a passband between about 0.1 to 10 s, the later version (SKD) between 0.1 and 20 s (see Figure 10). Using records of these instruments, already Solov'ev (1955) presented empirical evidence that the ratio  $(A/T)$  is a stable quantitative characteristic of surface wave maxima, independent of period in a wide range from local to teleseismic distances.

$M_{s\_BB}$  is calibrated with formula (4), only slightly modified from the original formula (10), for inserting directly measured velocity amplitudes in nm/s. The original formula (10) was published by a team of Czech and Russian authors (Vaněk et al., 1962; Karnik et al., 1962) and accepted by IASPEI in 1967 as the standard formula for  $M_s$  calculations.

Although formula (10) was originally proposed for the distance range  $2^\circ$  to  $160^\circ$  subsequent work indicates that it is more appropriate to use for distances larger than  $140^\circ$  the tabulated values published by Kondorskaya et al. (1981), which are reproduced in Table 4 of DS 3.1 in this Manual. The reason is the same as the reason that Lienkaemper (1984) used at distances  $>125^\circ$  instead of Gutenberg's (1945a) formula (9) the tabulated calibration values published in Richter (1958) (see Table 3 in DS 3.1), because they better account for the energy focusing effect towards the antipodes.

The Czech and Russian team that developed equation (10) (Vaněk et al., 1962; Karnik et al., 1962) measured the surface-wave maxima in a wide period range between some 2 s and 25 s. In Chapter 3 it is shown that  $V_{max}$  recorded in modern very broadband records may occur, although rarely, at periods well beyond 25 s, up to about 60 s. Accordingly the period range for  $M_s\_BB$  measurements has been extended now so that it is  $3\text{ s} < T < 60\text{ s}$ . The Czech and Russian team showed that the prevailing periods depend on distance (Vaněk et al., 1962). Their related Table (see Table 6 in DS 3.1) has been reproduced in the Wilmore (1979) Manual of Seismological Observatory Practice. The Wilmore (1979) Manual also includes the recommendation: "When the period differs **significantly** from the values in Table 3.2.2.1, it may be advisable not to use the data for magnitude determination." The issue of use of the  $M_s\_BB$  formula beyond the distance-dependent period ranges indicated in Table 6 of DS 3.1 still deserves special study.

The IASPEI proposed procedure for  $M_s\_BB$  determination has been extensively tested at the CENC, where it was applied to some 10,000 station readings of globally distributed earthquakes recorded by the broadband China National Seismic Network (CNSN) in the distance range between  $2^\circ$  and  $100^\circ$  (Bormann et al., 2009). Despite the large scatter of station-site period readings the general trend and range of periods published by Vaněk et al. (1962) has been confirmed down to local-regional distances and periods as short as 2 to 5 s. Additionally a trend of period increase with magnitude was evident (see also related Figures and discussions in Chapter 3). It is notable that the variance of  $M_s\_BB$  resulting from this test was somewhat smaller than the variance of  $M_s\_20$  (Table 5).

**Table 5** Average standard deviations of station magnitude estimates from average network event magnitudes for different scales. Data were taken from Bormann et al. (2007 and 2009). GRSN = German Regional Seismic Network, data by courtesy of S. Wendt; CNSN = China National Seismic Network. Note that CNSN SD values for  $M_s\_20$  and  $M_s\_BB$  relate to readings of equivalent Chinese magnitude standards of  $M_s7$  and  $M_s$ , respectively.

| Magnitude | Average SD (GRSN) | Average SD (CNSN) |
|-----------|-------------------|-------------------|
| mb        | 0.21              | 0.23              |
| mB_BB     | 0.15              | 0.21              |
| $M_s\_20$ | 0.12              | 0.26              |
| $M_s\_BB$ | 0.10              | 0.23              |

Although  $M_s\_BB$  and  $M_s\_20$  agree well whenever  $T$  at  $V_{max}$ , respectively  $A_{max}$ , is close to 20 s, differences may reach 0.5+ m.u. when  $T$  differs (depending on magnitude, travel-path and distance) significantly from 18-22 s (Figure 7).

**Figure 7** Difference between  $M_s\_BB$  and  $M_s\_20$  in relation to the period at which  $V_{max}$  was measured on the velocity broadband records. Data are based on GRSN station record readings (courtesy of S. Wendt, 2008).

In the study of Bormann et al. (2009) most of the  $V_{max}$  values of Rayleigh surface waves were observed outside the period range 18–22 s. This holds for 79% of the analyzed CNSN records and for 62% of the analyzed GRSN records (see Figure 7), although the latter include many more oceanic travel paths and rarely any record at epicenter distances below  $13^\circ$ , which are much more frequent in Chinese network records and typical for rather short-period Rayleigh-wave maxima on continents.

Since the two magnitudes are calculated with the same numerical attenuation relation, but surface-wave amplitudes from which  $M_s\_BB$  can be calculated are commonly larger at periods less than 18 s, the difference  $M_s\_BB - M_s\_20$  for earthquakes of  $M_s\_BB < 6.5$  tends to be 0.1 to 0.2 magnitude units, increasing with decreasing magnitude. But  $M_s\_20$  and  $M_s\_BB$  agree on average rather well for magnitudes above 6.5 (Figure 8). Similarly, both magnitudes agree on average rather well with  $M_w$  for magnitudes between 6.5 and 8+, but for  $M_w < 6.5$  the discrepancy between  $M_s\_20$  and  $M_w$  is about twice as large as that between  $M_s\_BB$  and  $M_w$ . The magnitude “bias” between  $M_s\_20$  and  $M_w$  had already been predicted by Kanamori and Anderson (1975) on the basis of theoretical dimension analysis and was empirically confirmed by Ekström and Dziewonski (1988). Recent data by Bormann et al. (2009) fully agree with the theoretically predicted trends for  $M_s\_20$  (Figure 9), but also showed that  $M_s\_BB$  reduces the  $M_s\_20$  “bias” for  $M_w < 6.5$  by half.

**Figure 8** Standard regressions SR1 and SR2 as well as orthogonal regression between  $M_s_{20}$  and  $M_s_{BB}$ .  $R_{XY}$  – correlation coefficient,  $RMSO$  – orthogonal root-mean-square error. Cut-out from Figure 11 in Bormann et al. (2009), Bull. Seism. Soc. Am., **99** (3), p. 1881, © Seismological Society of America.

**Figure 9** Comparison between CNSN data of standard  $M_s_{20}$  with Global Centroid Moment Tensor solutions  $M_w$  and the theoretically predicted trends by Kanamori and Anderson (1975). Since, according to Figure 14,  $M_s_{BB}$  tends to be larger than  $M_s_{20}$  for  $M_s_{BB} = M_w < 6.5$ , its bias with respect to  $M_w$  is halved in this range.

However, what is or is not considered a bias of a given scale in relation to another is often a matter of perspective or preference given to certain more physically based seismic parameters such as seismic moment or released seismic energy. For example, the reason that  $M_s_{20}$  scales as 1.5  $M_w$  for small earthquakes is that  $M_s_{20}$  scales then as  $\log M_0$  for these earthquakes. So  $M_s_{20}$  behaves in a very predictable way with respect to the moment of small earthquakes, and many seismologists find this desirable. Developers of the  $M_s(V_{max})$  magnitude (Bonner et al., 2006) specifically emphasize the proportionality of  $M_s(V_{max})$  to  $\log M_0$  as evidence that  $M_s(V_{max})$  is a valuable magnitude. Future comparison of  $M_s_{BB}$  and  $M_s(V_{max})$  data, which are now routinely calculated at the USGS/NEIC, will better reveal the benefits or drawbacks, compatibility or complementarity of these two surface-wave magnitudes based on variable period data that are obtained by very different methodologies. In summary: of the two currently adopted IASPEI  $M_s$  procedures,  $M_s_{BB}$  agrees best with the original definition and intention of the  $M_s$  equation derived by Vaněk et al. (1962).  $M_s_{BB}$  is simply measured on unfiltered velocity broadband records, and several studies have shown that it has lower standard deviations than  $M_s_{20}$ (IASPEI). It is also applicable to many more surface wave records in a wider (down to local) distance range than  $M_s_{20}$ (IASPEI). Moreover, for magnitudes below 6.5  $M_s_{BB}$  is closer to  $M_w$  than  $M_s_{20}$ , irrespective of whether or not this is considered desirable.

#### 4.6 $mb_{Lg}$

Nuttli (1973) originally developed  $mb_{Lg}$  for eastern North America, and he proposed  $mb_{Lg}$  equations for that region that would be reasonable approximations to equations having the form of equations (7) and that are linear in  $\log(\text{epicentral distance})$ . The approximate

equations of Nuttli(1973) implicitly incorporate an eastern North America attenuation function, and the equations are used by many agencies to assign  $mb\_Lg$  to eastern North American earthquakes. The approximate equations of Nuttli (1973) yield  $mb\_Lg$  that are about 0.1 magnitude units smaller than those of the proposed standard procedure, when  $\gamma = .00063 \text{ km}^{-1}$  in equations (7). We propose the procedure of Nuttli (1986) as standard, in preference to the procedure of Nuttli(1973), because the former is transportable to regions with attenuation different than that of eastern North America (Nuttli, 1986; Patton, 2001).

#### 4.7 $M_w$

The recommended standard formulas for calculating  $M_w$  via seismic moment  $M_0$  follows directly from the way how it has been systematically derived from the basic assumptions made about the ratio between seismic energy and scalar seismic moment release, average rigidity and stress drop in the source volume and the Gutenberg-Richter relationship between  $\log E_s$  and  $mB$  on the one hand and  $mB$  and  $M_s$  on the other hand (see Bormann and Di Giacomo, 2011).

### 5 Deviations from the recommended measurement standards

The measurement standards specify the frequency response, the period range of measurement, the measurement time-window, the calibration function to be used and how amplitude measurements should be made. Inevitably, different seismological centers will see the desirability to adjust the procedures to address special circumstances. Paradoxically, a chief value in defining standard procedures is to codify a baseline procedure from which the desirability of future improvements to the procedures may be examined. In the following we illustrate examples of the types of *changes in standard procedures that may be acceptable without necessitating that the magnitudes computed with the changed procedure be assigned a different nomenclature*. An alternative procedure may also be preferable to a standard procedure in a particular region if it is more consistent with regional attenuation properties. In this last situation, however, magnitudes computed with the alternative procedure should usually be described with a different nomenclature than magnitudes computed with the standard procedure. For some guidance see IS 3.2.

The first-order criterion to judge whether any alternative procedure is equivalent to a standard procedure is whether or not the alternative procedure yields in a wide magnitude range results that deviate on average less than 0.1 m.u. from those resulting from the strict application of the proposed measurement standards. Alternative proposed measurement parameters will for many purposes be acceptable as substitutes for the standard procedures if it can be confirmed by a representative comparative data set (see IS 3.4), that they do not significantly bias the magnitudes beyond this limit. From a practical standpoint, a changed procedure may be preferable to a standard procedure if, in addition to producing results that are not biased with respect to a standard procedure, it produces results with less scatter than the standard procedure or if it allows unbiased magnitudes to be determined for distance ranges or seismic-noise conditions in which the standard procedure is not appropriate.

The measurement of amplitudes and periods from digital signal by an automatic computer algorithm poses problems that are not addressed by the IASPEI standard procedures. Automatic pickers may require modification of the procedures in order to minimize picking of amplitudes in noisy or prior-shock-contaminated seismograms that would be rejected as

unsuitable by a seismologist who is making measurements with interactive processing software. In cases when a standard procedure is modified to suppress measurements made from noise, the suitability of the modification should be tested with respect to magnitudes that are measured interactively.

### 5.1 Variations in filter parameters acceptable for determining standard ML, mb, and Ms<sub>20</sub>

Figure 10 depicts the responses of seismographs represented in Figure 1 along with responses of several additional seismographs from which magnitude measurements have commonly been made. Unlike Figure 1, where gains are normalized to unity, the relative values of gains in Figure 10 are the ones implemented in the data acquisition and processing system at the Central Seismological Observatory SZGRF of the BGR in Germany (<http://www.szgrf.bgr.de/>; last accessed 11 March 2012) and the Seismic Handler Motif (SHM) software. We will in the following discuss their suitability for determining standard magnitudes.

**Figure 10 Left:** Relative displacement gain of simulation filter responses implemented in the Seismic Handler (SHM) software for analyzing records of the Gräfenberg (GRF) array and of stations of the German Regional Seismic Network (GRSN); **right:** Responses of different generations of velocity broadband seismographs STS1(GRF) (old version used at the GRF array), STS1 (VBB) (advanced version as used in the IRIS global network) and STS2. Figure modified from Chapter 11 to same ordinate-abscissa scale.

#### 5.1.1 ML

According to Figures 1 and 10 (left-hand panel) the response of the Wood-Anderson (WA) seismograph decays with decreasing frequency below 0.5 Hz only with the second order. Accordingly, sea or ocean storm microseisms with frequencies between  $0.1 \text{ Hz} < f < 1 \text{ Hz}$  are

not very efficiently suppressed and the signal-to-noise ratio in WA records may become very low for small earthquakes. By increasing the corner frequency of the WA high-pass simulation filter, and/or by steepening its roll-off towards lower frequencies, the SNR may be significantly improved and enable the measurement of ML correctly down to very small earthquakes, provided that the corner frequency of the signal spectrum is still well within the plateau of the modified WA response. Uhrhammer et al. (2011) have used this strategy to enhance SNR for purposes of measuring ML in California.

### 5.1.2 mb

In section 4.3 we have already extensively discussed the effect of different short-period responses, presented in Figure 3, on mb estimates. With reference to the average seismic source spectrum presented in Figure 1 of Bormann et al. (2009) (see also Chapter 3) we concluded that for magnitudes between about 3.5 and 5.5, the corner frequency of the radiated source spectra and thus the maximum of radiated seismic energy is expected to vary on average between some 0.5 and 4 Hz. When both the relative bandwidth as well as the response peak frequencies within this range differ significantly from the WWSSN-SP standard response then this will result in mb estimates that may differ more than 0.1 m.u. from the IASPEI standard mb as it is the case for mb(IDC). However, the PIDC response (see Figure 3) allows to measure mb still reliably for smaller events than one can measure on WWSSN-SP records, because of its steeper roll-off and thus improved SNR towards lower frequencies and its peak magnification at 2 times higher frequency. Thus it may be an acceptable substitute for the IASPEI standard WWSSN-SP response for  $mb < 4$ . A rigorous comparative test is not yet available but would be worthwhile to undertake.

However, also transfer functions for classical WWSSN short-period seismograph differed somewhat for different magnification settings. In addition, different WWSSN-SP simulation filters may have been implemented in different analysis software. For example, the Seismic Handler Motif (SHM) software, developed by Klaus Stammli, BGR Hannover, assumes beyond the response peak only a first-order decay of gain with higher frequencies (see left panel of Figure 10 and poles and zeros in Tab. 11.3 of Chapter 11), in contrast to the decay with second order for frequencies  $f > 3$  Hz of the IASPEI adopted WWSSN-SP standard response (Figure 1 and Table 1 in this IS). This effectively means a slight reduction of the relative bandwidth RBW and thus of the measured amplitudes (see Chapter 4). In conjunction with the upgrading of the SHM software to accommodate the new IASPEI standard responses Klaus Stammli filtered about 15,000 P waveforms both with the old SHM and the new IASPEI WWSSN-SP response. He found that mb(IASPEI) would on average be 0.033 m.u. smaller than mb measured on old SHM WWSSN-SP simulated records (with a standard deviation of  $\pm 0.06$  m.u.) (see Figure 11). Thus, filter-wise the older mb data reported by the BGR to international data centers would still be within the tolerance limit of 0.1 m.u. and thus be acceptable as standard mb values, provided that the variable measurement-time window and peak-to-trough/2 rules have been applied as well. The latter is generally the case in the interactive SHM mode.

**Figure 11** Difference between mb values calculated with amplitudes and periods measured on simulated WWSSN-SP records filtered with slightly different responses: mb(BGR) with the WWSSN-SP response in the left panel of Figure 10 and the poles and zeros in Table 11.3 ?? of Chapter 11 and mb(IASPEI) with the respective response curve and parameters in Figure 1 and Table 1 of this IS 3.3.

### 5.1.3 Ms<sub>20</sub>

According to the standard procedure Ms<sub>20</sub> should be measured on records with the WWSSN-LP response. Yet the instrument's gain decays with increasing frequency only by first order. Therefore, ocean microseisms with periods between approximately 4 to 8 s may result in very low SNR for measurement of surface-waves with periods around 20 s from weak earthquakes. This limits the lower magnitude threshold down to which the mb-Ms<sub>20</sub> criterion for discriminating between natural earthquakes and underground nuclear explosions can be applied (see Fig. 11.22 ??? in Chapter 11 of this Manual). Therefore, a former global U.S. network of Seismic Research Observatories (SRO), operating between 1974 and 1993, used a modified SRO-LP response with much steeper flanks and an additional 6 s microseism notch-filter. This resulted in a rather narrow high-gain 20 s band-pass (see left-hand panel of Figure 10). The difference in shape as well as in the poles and zeros with respect to the WWSSN-LP response is striking (see Table 11.3 ??? in Chapter 11 of this Manual). When compared with WWSSN-LP and velocity broadband records, SRO-LP records look rather smooth and less noisy (Figure 12).

**Figure 12** Comparison of an unfiltered STS2 velocity broadband record of an earthquake in the North Atlantic Ocean at station CLL ( $D = 26.8^\circ$ ,  $mb = 5.7$  (GSR)) with the respective WWSSN-LP and SRO-LP filtered records (courtesy of S. Wendt, 2012).

One might expect from so different responses and record appearance significant differences in long-period magnitude estimates. This, however, is not the case for the band-limited  $M_s_{20}$ . Its measurement periods between 18 and 22 s are comparably well covered by the peak-response ranges of both WWSSN-LP and SRO-LP. Therefore, the average relationship between  $M_s_{20}$  measured on WWSSN-LP and SRO-LP records is indeed 1:1 over the large range of 4 magnitude units with a standard deviation of only 0.03 m.u. (Figure 14), although the respective surface-wave record trains might look quite different (Figure 13a). The data scatter in Figure 14 would only increase somewhat, if WWSSN-LP records with rather low SNR and thus significant amplitude reading errors would be included into the statistics as well. But for surface-wave trains with  $SNR \leq 1$  in unfiltered velocity and/or WWSSN-LP records it might be possible to determine a reasonably good  $M_s$  estimate only from SRO-LP records (Figure 13b).

**Fig. 13** Unfiltered velocity-proportional STS2 broadband records and related WWSSN-LP and SRO-LP filtered records of the surface-wave train of two earthquakes in the North Atlantic Ocean recorded at station CLL, Germany:

- a)** 06 Oct. 2011, OT = 00:39:31.0, epicentral distance  $D = 26.8^\circ$ ,  $m_b = 5.7$ ,  
 $M_s_{BB} = 5.6$ ,  $M_s_{20}$  (WWSSN-LP and SRO-LP) = 5.5;
- b)** 06 Oct. 2011, OT = 01:33:33.2, epicentral distance  $D = 26.7^\circ$ ,  $m_b = 4.5$ ,  
 $M_s_{20}$  (SRO-LP) = 4.5.

The solid dots mark the amplitude measurement times for  $M_s_{BB}$  (black) and  $M_s_{20}$  (blue and red). The open blue circle marks the maximum trace amplitude on the WWSSN-LP record at  $T = 15.7$  s, which would correspond with  $V_{max}$  on the unfiltered STS2. (Acknowledgment: the figure has been compiled and complemented based on records that were kindly provided by S. Wendt (2012).

From Fig. 13a) one recognizes that the trace  $A_{max}$  is measured earliest on the SRO-LP record at  $T = 20.3$  s and about 80 s later on the WWSSN-LP record within the  $M_s_{20}$  period window at  $T = 18.9$  s. But the magnitude values are the same, although both being smaller by 0.1 m.u. than  $M_s_{BB}$ , which is measured at  $T = 15.9$  s, about two minutes later than on the SRO-LP record. One should note, however, that in fact also the maximum amplitude in the WWSSN-LP surface-wave train does not occur within the 18–22 s period window, but rather at  $T = 15.7$  s, i.e., close to the period of 15 s at which the WWSSN-LP response has its largest magnification. And when determining  $\log(A/T)_{max}$  with  $T = 15.7$  s then one gets the same  $M_s = 5.6$  as directly with  $M_s_{BB}$ . Thus, limiting  $M_s$  determination on WWSSN-LP records strictly to the narrow period range of 18–22 s is rather arbitrarily fixed to the 20 s spectral amplitude maximum and not related to the maximum record trace amplitude. Yet the 20 s spectral amplitudes are best recorded by a proper SRO\_LP filter centered at 20 s.

**Figure 14** The 1:1 relationship between vertical component maximum Rayleigh wave  $\log(A/T)$  values measured at periods between 18 and 22 s on SRO-LP and WWSSN-LP records using the IASPEI standard magnitude reference data set (see IS 3.4 of this Manual; courtesy of Siegfried Wendt, 2011).

Figure 14 confirms that  $M_s_{20}(\text{SRO-LP})$  is fully compatible with standard  $M_s_{20}$ . Accordingly, its amplitudes should be reported as  $IAMs_{20}$ . Since SRO-LP records have in any event a better SNR than WWSSN-LP records this would even justify to declare SRO-LP as the best suited response for standard  $M_s_{20}$  measurements. However, up to now, this filter is less frequently implemented than WWSSN-LP in seismic waveform analysis programs. An exception is the program Seismic Handler (SHM) by Klaus Stammer which can be downloaded from <http://seismic-handler.org/portal>. Chapter 11 and DS 11.1 to 11.3 present many SRO-LP filtered records in comparison to other standard filtered and unfiltered BB records.

In summary: For  $M_s_{20}$  determination with the predefined 18 to 22 s period range for measuring A the exact implementation of the WWSSN-LP standard response parameters is not critical, provided that these periods fall within the passband range of any alternative response. Note, however, that neither SRO-LP nor WWSSN-LP narrowband records are suitable to measure correct broadband  $M_s_{BB}$ , which necessitates records with a velocity proportional response which covers the whole range of periods for which this magnitude may be calculated ( $T = 3$  to 60 s), yet at least up to about 40 s. The velocity maximum  $V_{\max}$  of Rayleigh waves occurs only seldom at longer periods. Examples of suitable velocity broadband responses are given in the right-hand panel of Figure 10 with STS2 and STS1-VBB. These frequency ranges are also covered by several more recent broadband systems from the UK, USA and China (see DS 5.1 in this Manual).

## 5.2 The influence of the measurement time-window on mb and mB estimates

In the above definition of the mb and mB standards it is stated that these body-wave magnitudes should be “...calculated from the maximum trace-amplitude in the **entire P-phase train** (time spanned by P, pP, sP, and possibly PcP and their codas, and ending preferably before PP).

Gutenberg has derived calibration functions for P and PP waves but not for PcP and depth phases. PcP amplitudes are generally smaller than P amplitudes, especially broadband ones

(see, e.g., record examples for event 6 in DS 11.2). So there is no magnitude bias likely from measuring PcP instead of P.

Depth phases were considered by Gutenberg as part of the primary phases with commonly smaller (and then for magnitude estimates irrelevant) amplitudes because of reflection and/or conversion losses as well as extra attenuation along the additional segment of travel. For shallow earthquakes a clear discrimination between superimposed direct and depth phases is difficult anyway and usually beyond the possibilities of routine seismogram analysis. Yet, depth phases may become even larger than their primary phases, as confirmed by both observations (e.g., Figs. 2.62-2.65 in Chapter 2, and Fig. 11.16 ??? in Chapter 11) and synthetic modeling (e.g., Langston and Helmberger, 1975).. The great variability of amplitudes of both P and its depth phases is a source-mechanism dependent function of take-off angle and azimuth and therefore varies with distance and azimuth of the recording station with respect to the source radiation pattern. Procedures such as that of Choy and Boatwright (1995) for calculating released seismic energy  $E_s$  and energy magnitude  $M_e$  assume that the P-wave train consists of direct P plus depth phases and they apply source-mechanism dependent corrections. Since the take-off angles of direct P, pP and sP differ strongly, the inclusion of the depth phases into the mb and mB estimates has an averaging stabilizing effect which reduces possible bias due to strongly variable P-wave radiation when only a limited number of observations with insufficient azimuthal coverage is available.

Also broadband PP amplitudes are usually smaller than those of direct P and especially depleted in higher frequencies because of their longer overall ray path with additional segments through the stronger attenuating upper mantle (see, e.g., record examples of events No. 6 and 7 in DS 11.2). Moreover, onsets of PP are usually well enough separated from P, easy to identify by means of their differential travel-time difference (see differential travel-time curves in Figure 4 of EX 11.2), have their own calibration values (see DS 3.1 in this Manual) and thus are not a biasing factor for P-wave based mb or mB estimates. However, the rupture duration of great earthquakes may be so long that significant amounts of P-wave energy are still arriving at the theoretically expected first arrival time of PP. Should then the measurement time-window **preferably end before PP**, as recommended by the standards? Not necessarily, if good reason speaks against it and can be proven by measurement. Figure 15 gives an example for the application of a simple technique, which allows to constrain the appropriate time window in which to search for the maximum P amplitude. It measures the duration  $d$  of high-frequency radiation, which is mainly generated at the progressing rupture front. Thus  $d$  is also a rough estimate of the rupture duration  $T_R$  but tends to be longer than  $T_R$  because of the deliberate inclusion of the depth phases of P and their codas. The technique (for details see (Bormann and Saul, 2008) resembles those of Hara (2007a and b), Lomax et al. (2007), Lomax and Michelini (2009). It computes the envelopes of individual, velocity-proportional P-wave records filtered in a frequency band between 1 and 3 Hz. From the average of all envelopes, aligned by P onset, the time lag is determined at which the amplitude falls below 40% (energy-wise to 16%) of its maximum, thus giving a robust estimate of the approximate duration  $d$  of the whole P-wave train. It allows to constrain the time window for mb and mB measurements, even in the presence of later phases like PP, which contribute to the high-frequency signal much less than direct P and its depth phases. This is especially useful in automated setups, but simple visual time window selection on the SP-filtered record by an experienced analyst before measuring  $A_{max}$  for mb calculation yields practically the same result.

**Figure 15** Vertical-component broadband record of the Mw7.7 Java earthquake of 2006 at station PMG. The grey shaded area is the envelope of the positive amplitudes of the velocity-proportional high-frequency (1-3 Hz) filtered P-wave record (plotted at larger scale). Vmax of P is searched within the time-window from the P onset and the time at which the envelope amplitude falls below 40% of the maximum envelope amplitude. This part of the record trace is shown in black. The Pmax, to be measured for mB determination occurs some 140 s after the first P onset, with a period around 10 s, some 50 s later than the theoretically calculated first onset of PP. In contrast, according to the SP envelope, Pmax in the SP record, to be measured for mb, appears already 40 s after the P onset. (Amended cut-out from Figure 3 in Bormann and Saul (2008), *Seism. Res. Lett.*, **79**(5), p. 700, © Seismological Society of America.)

Kanamori (2006), investigating the seismic energy release of the great Mw9.3 2004 Sumatra earthquake, also extended the integration window over the whole P-wave train into the PP range with an estimated bias in  $E_s$  that would correspond to less than 0.1 m.u. in Me.

### 5.3 The influence of the calibration function on the magnitude estimates

The *Magnitude WG* had been entrusted solely with proposing unique measurement standards but not with the development or proposal of new calibration functions. For most magnitude types, the *WG* adopted a strategy of identifying classical, already widely used, attenuation functions as the standard function, with expectation that these functions would be improved upon in the future. The *WG* endorsed the commonly used practice of using the classical attenuation functions as reference base lines for scaling improved global and regionally specific attenuation functions. Some of such alternative functions exist already but in most cases no agreement has so far been reached for their universal acceptance and use. Below we briefly comment on the current and some of the potential alternative future calibration relationships in order to understand their main differences and possible effects in the case of change.

#### 5.3.1 ML calibration function

The new IASPEI ML standard replaces the old Richter calibration function by the expanded Hutton and Boore (1987) relationship, modified for the Uhrhammer and Collins (1990) recalibration of the Wood Anderson seismograph. The difference from the original Richter formula and its tabulated calibration values has been plotted in Figure 2 (with comments), and the benefits of scaling other regional calibration functions to the H-B formula better at shorter distances than 100 km have already been discussed in section 4.1 of this IS (see also Fig. 3.30

in Chapter 3). Yet, ML differs from most of the other magnitudes in that most ML values are already calculated with region-specific formulas, and they are appropriately designated by unique formulas. The most important principle to establish with ML is that the standard amplitudes are measured through the WA filter and that these amplitudes should be reported in bulletins.

### 5.3.2 mB\_BB and mb calibration functions

Both standard magnitudes are still calibrated with the original revised Gutenberg-Richter (1956a) Q-values for vertical component medium-period P waves (QPZ). The original diagrams and tabulated values are given in DS 3.1, the tabulated values resulting from the USGS scan of the QPZ diagram are presented in Table 2 of this IS for the distance range 20° to 100° as a function of hypocenter depth. The original QPZ( $\Delta$ , h) values were given for the distance range 5° to 110°. However, the values in the beginning of the Earth's core shadow zone of P beyond 100° and in the strongly upper mantle affected distance range between 5° and 20° are considered not yet reliable enough for global application. These problems have already been pointed out much earlier by Evernden (1967) and Booth et al. (1974). A detailed discussion of this issue goes far beyond the scope of this IS and still requires many dedicated investigations which will greatly benefit from the global introduction into observatory practice of the proposed measurement standards. Figure 16, presented in an AGU poster by Saul and Bormann (2007), has been derived from global velocity broadband IVmB\_BB amplitude measurements. It may just serve as an illustration of what one can expect, namely a much smoother distance dependence of QPZ in general and major revisions, most likely regionally variable, for distances below 20°. That is, why the current global standards do not yet propose to calculate mb and mB\_BB at distances below 20°. We encourage, however, to measure and report to international data centers related amplitude values as Iamb and IV\_mB\_BB also if they have been measured at distances less than 20° in order to collect masses of standardized data from all seismic regions for investigating such regional variations in amplitude-distance relationships.

**Figure 16** Comparison between the original Gutenberg-Richter (1956a) Q values for vertical component P waves from earthquakes at depth < 70 km with preliminary data based on broadband velocity P-wave amplitude measurements by Saul and Bormann (2007). The Saul and Bormann curve is associated with curves representing +/- the standard error, which is also represented in the chart at the top of the figure.

Veith and Clawson (1972) developed an alternative vertical-component short-period body-wave scale  $P(\Delta, h)$ , which was scaled to the level of the Gutenberg-Richter  $Q(\Delta)_{PZ}$  for surface focus.  $P(\Delta, h)$  is based on WWSSN-SP records from strong explosions. The calibration curves for deeper sources (see Figure 2 of DS 3.1) were calculated using an attenuation model developed by Veith and Clawson (1972). There are large differences between the Gutenberg-Richter and the Veith-Clawson calibration function for deep earthquakes, up to 0.6 m.u. The Veith and Clawson (1972) body-wave scale has been adopted by the CTBTO/IDC, and differences between the Veith and Clawson  $P(\Delta, h)$  values and the Gutenberg and Richter  $Q(\Delta, h)$  values are, for intermediate-depth and deep-focus earthquakes, a significant component of the discrepancy between the  $mb(\text{NEIC})$  and  $mb(\text{IDC})$  discussed in section 1 (Murphy and Barker, 2003).

In general, there is a need to develop improved global and region-specific calibration functions for both  $mb$  and  $mB$ , or to confirm some of the various calibration functions that have already been proposed. In addition to the previously discussed global calibration functions of Gutenberg and Richter (1956a) and Veith and Clawson (1972), Murphy and Barker (2003) have tabulated proposed global calibration functions from  $0^\circ$  to  $180^\circ$ , and Christokov et al. (1983), Lilwall (1987), and Rezapour (2003) have tabulated proposed global calibration functions for distances beyond  $20^\circ$ . The effect of frequency dependence on the attenuation of P-waves must also be considered. The ability to confidently use  $mB$  calculations from the near regional distance range would allow seismologists to exploit still better the superior potential of  $mB$  for yielding less saturating magnitude estimates of strong earthquakes in real time for tsunami early warning and emergency assistance purposes. Greater confidence in the short-period magnitudes assigned to deep earthquakes might shed light on the source physics of these earthquakes. The future work will strongly benefit from world-wide adherence to the newly recommended IASPEI measurement standards, because they will significantly reduce data scatter due to non-standard procedures, thus bringing out more clearly biases in currently assumed empirical and theoretical Earth models.

### 5.3.3 $Ms_{BB}$ and $Ms_{20}$ calibration function

The empirical stability and global representativeness of  $Ms_{BB}$  measurements (see section 4.5) notwithstanding, there are a number of factors that would be expected to produce biased station  $Ms_{BB}$  in some seismotectonic settings. “Biased results”, in the sense used here, would typically be  $Ms_{BB}$  values at regional distances that are significantly different than the values at teleseismic distances. Marshall and Basham (1972) summarize a number of such factors. For example, Rayleigh wave amplitudes of periods near 10s, from which  $Ms_{BB}$  might be measured at  $\Delta \sim 15^\circ$ , are expected to be sensitive to differences in velocity structure and attenuation properties of propagation paths, particularly to the difference between a continental path and an oceanic path, but also to the differences between some types of continental path. Other potential sources of bias are the difference between the source spectrum at long and short periods, which will itself be different for earthquakes of different  $M_w$ , and the sensitivity of the Rayleigh-wave spectrum to focal depth and focal-mechanism (Tsai and Aki, 1970). A mass collection of standardized  $Ms_{BB}$  and related amplitude and period values in the years to come will provide a good basis for investigations on possible  $Ms_{BB}$  biases associated with particular seismotectonic environments.

More is already known about the systematic distance-dependent biases of  $Ms_{20}$  when scaled with the IASPEI recommended standard  $Ms$  formula (10) according to Vaněk et al. (1962) (von Seggern, 1977; Herak and Herak, 1993; Rezapour and Pearce, 1998). As noted

previously, the IDC of the CTBTO calculates already its  $M_s$  with formula (18) of Rezapour and Pearce (1998) (see DS 3.1 and Chapter 17 of this Manual) and is successfully calculating  $M_s$  at near-regional and regional distances, in addition to teleseismic distances. A significant component of the distance-dependent bias of formula (10), when used for scaling amplitude measured around 20 s only, is likely to arise from the fact that constants in the adopted  $M_{s\_20}$  attenuation relation, equation (3)/equation (10), were determined with data over a broader range of periods with average  $T$  increasing significantly as a function of epicentral distance (see Fig. 8 in Bormann et al., 2009).

Bormann et al. (2009) showed that the difference of relation (10) to relations given by Herak and Herak (1993) or Rezapour and Pearce (1998) reduces to less than 0.1 m.u. between  $50^\circ$  and  $170^\circ$  when using instead of the calibration term in the IASPEI  $M_s$  formula the respective tabulated calibration values in Table 4 of DS 3.1 of this Manual. Using tabulated calibration values instead of an approximated formula was proposed already earlier by Vaněk (1995) with reference to the publication about the homogeneous magnitude system (HMS) studies for Eurasia (Christoskov et al., 1991). Yet between  $1^\circ$  and  $130^\circ$  tabulated and formula-derived Prague-Moscow calibration values agree within 0.02 m.u. The global introduction of a revised  $M_{s\_20}$  specific calibration scale may be reconsidered again after several years of standardized  $M_{s\_20}$  measurements are available.

### 5.3.4 How amplitude, period and measurement time should be measured

The first sentence in section 3.2, which outlines the IASPEI recommended measurement standards, reads: “The amplitudes used in the magnitude formulas below are to be measured as one-half the maximum peak-to-adjacent-trough (sometimes called “peak-to-peak”) deflection of the seismogram trace.” This recommendation is based on common practice with analog records. Analog records had a very limited dynamic range of about 30-40 db. Most trace amplitudes were measured with low signal-to-noise ratio in the millimeter range, sometimes only 2- to 3-times the thickness of the record trace and with the zero line difficult to fix. By measuring one-half peak-to-trough, relative reading errors could be reduced. This may be the reason why Richter, who initially (Richter, 1935) measured zero-to-peak amplitudes changed later (Gutenberg and Richter, 1956b) to one-half peak-to-trough measurement. This practice also reduces measurement errors when short-period signals are riding over long-period noise or the surface-wave train of a previous earthquake, making it difficult to fix the zero reference line. Moreover, the majority of record signals, especially in narrowband records of the WWSSN-type, and dispersive surface-wave trains anyway, appeared rather symmetric. Empirically, both one-half peak-to-trough and zero-to-peak reading practices yield in many circumstances the same magnitude values to within 0.1 m.u. (Rezapour and Rezaei, 2011). Thus it became the dominant practice in older times and continued to be also the easiest and rather unambiguous way of amplitude measurement in modern interactive seismogram analysis programs, because an experienced analyst will always be able to recognize most easily and pick correctly the largest peak and adjacent trough. Accordingly, almost all reading examples presented in the 1979 Willmore Manual of Observatory Practice as well as in the first edition of the NMSOP favor the (P-to-T)/2 approach of amplitude.

However, the problem is more complex. In the first edition of the NMSOP there is also an example given for amplitude measurement on a strongly asymmetric P-wave onset, as they often appear on broadband displacement records. The more broadband a displacement record is, the more asymmetric are the records of body-wave onsets (see the two lowermost record

traces in Fig. 4.13 and Fig. 4.15 of Chapter 4). Many classical medium- to long-period analog seismographs, widely used for measuring mB and Ms in the past, such as those of type Wiechert, Mainka, Galitzin and Kirnos, were more or less broadband displacement recorders. NMSOP then recommends to measure the largest half-swing amplitude from the zero line.

In this context one should be aware that an ideal seismic rupture does not produce an harmonic oscillating ground displacement. Rather, when the rupture can be approximated in a time-displacement diagram by a ramp function in the *near-field* range then this is observed in the *far-field* as a more or less bell-shaped and single-sided displacement pulse (see Fig. 2.4 in Chapter 2), which, if directivity is present, may have asymmetric rise and decay times (e.g., the Brune model displacement pulse in Fig. 4.17 of Chapter 4) Only its time-derivative, i.e., the far-field ground-motion velocity, is a two-sided oscillation with comparable amplitudes. Also narrow-band records in general as well as acceleration and surface-wave records show more symmetric oscillations. The differences in the symmetry of oscillations are very obvious, when comparing in Fig. 4.18 of Chapter 4 the unfiltered velocity broadband and the narrow-band short-period WWSSN-SP and long-period SRO\_LP records with the Kirnos and WWSSN-LP displacement records.

Therefore, many algorithms for automatic record analysis prefer zero-to-peak (or trough) measurement, e.g., the current version of SeisComp3 (Hanka et al., 2010) and used for the mB study by Bormann and Saul (2008). Zero-to-peak (trough) measurement can be more easily and unambiguously implemented, even a moving zero-line can most easily be determined by a moving long-term average and de-trending algorithm. Measuring the maximum amplitude between two zero crossings avoids the risk of getting trapped in a secondary minimum or maximum when looking for the largest adjacent trough (or peak).

Clearly, although the *Magnitude WG* has specified a procedure for measuring amplitudes, there is not consensus in the seismological community on the question of optimum procedure for amplitude measurement. Comparative measurements of amplitudes for standard mb, mB\_BB, Ms\_20 and Ms\_BB using both the peak-to-trough/2 and the zero-to-peak (or trough) approach are currently still under way and will be reported soon in a related section of the revised Chapter 3 of this Manual.

The new IASPEI recommended procedure for determining periods differs from the procedure that was commonly used with analog instruments and that is recommended in the 1979 Willmore Manual of Observatory Practice as well as in the first edition of the NMSOP, namely, that period should be read by measuring the time difference between the two neighboring maximum peaks or troughs. The newly recommended procedure -- "...periods are to be measured as twice the time-intervals separating the peak and adjacent-trough from which the amplitudes are measured" -- would have been impracticable using large amplitude analog records with fixed low time resolution and the difficulty to project precisely the time position of the peak down to the level where the time difference to the trough had to be measured. But most modern interactive analysis programs can now perform this easily and give the time of the zero-crossing between the peak and adjacent-trough as the amplitude-phase arrival-times. A modern zero-to-peak amplitude measuring algorithm would use neither the procedure recommended in the earlier manuals nor the current IASPEI recommended procedure: a zero-to-peak algorithm would measure the double time difference between the zero crossings relating to the measured maximum amplitude as period and give the time of the peak position itself as the measurement time. The fully automatic procedure of amplitude and period measurement at the IDC of the CTBTO determines even the period from the three half

periods between which the maximum amplitude has been measured (see Fig. 17.9 in Chapter 17 of this Manual).

For all the IASPEI magnitudes except *mb*, the value of the magnitude does not actually depend on the measured period. In fact, also *mb* could be measured directly via *V<sub>max</sub>* with likely comparable or even better precision than the standard procedure (currently under investigation) after convolving the broadband velocity record directly with the WWSSN-SP response. The cataloging of *T* is, however, important because *T* provides useful supplemental information that can help assess the reliability of a station magnitude measurement and because *T* for some magnitude-types (*mB\_BB* or *Ms\_BB*) contains information about the seismic source that is independent of the information provided by amplitude. Alternative strategies for measuring *T* (e.g., Boore, 1986; Kanamori, 2005) may provide estimates of *T* that are more informative for some purposes (e.g. engineering seismological) than those provided by the IASPEI procedure.

## 6 Summary

The information sheet outlines both the aim and the rationale of the IASPEI (2005 and 2011) recommended measurement procedures for widely used magnitude scales, and emphasizes the need for a unambiguous unique standardized nomenclature for reported and published amplitudes and calculated magnitudes. The new IASPEI magnitude formulas are presented and the essentials of the procedures and parameter ranges outlined, explained in their historical development, critically analyzed with respect to alternative procedures, their significance, range of tolerance and acceptable modifications. The advantages of the (in western countries still uncommon) broadband body and surface-wave magnitudes *mB* and *Ms\_BB* as compared to the bandlimited magnitudes *mb* and *Ms\_20* are highlighted.

Also stressed is the need for overlapping comparative measurements at seismic stations and analysis centers in conjunction with the implementation of the new standard procedures. Previous and the newly recommended standard procedures should be applied to the broadband waveform data from an IASPEI authorized set of reference events and their results be analyzed statistically. As an example of such a comparison the results of *Ms\_20* determinations on simulated WWSSN-LP and SRO-LP records, respectively, are presented, proving that they yield identical results. Guidelines for carrying out and documenting the results of such a comparative test are presented in IS 3.4.

Finally, future research into improving magnitude calibration functions, especially in the local and regional distance ranges, is strongly encouraged. It is hoped that such investigations will greatly benefit from the expected forthcoming masses of new data based on the agreed IASPEI measurement standards which are hoped to significantly reduce data scatter due to inconsistent or incompatible procedures of magnitude measurements.

## Acknowledgments

We are indebted to Members of the IASPEI Working Group on Magnitude Measurements and others who have essentially contributed to the discussions, consensus and results presented above, or made Figures available for this information sheet, in particular Siegfried Wendt, Joachim Saul and Klaus Stammer. We thank George Choy and Morgan Moschetti for

helpful reviews. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

## 1. Introduction

1.) The authors are Co-chairman (P. B.) and member (S. W.) of the IASPEI Working Group on Magnitude Measurement and entrusted with promoting the widest possible implementation and comparative testing of recent IASPEI/CoSOI summary recommendations of standard procedures for widely used magnitude measurements (see **IS 3.3** and [http://www.iaspei.org/commissions/CSOI/Summary\\_WG-Recommendations\\_20110909.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG-Recommendations_20110909.pdf))

2.) The current IASPEI standard magnitude reference data set allows to train yourself in the determination of the four **teleseismic magnitude standards** mb, mB\_BB, Ms\_20 and Ms\_BB. Read these related recommendations thoroughly before embarking on the exercise outlined below. The reference data set and guidelines will in a later version of this IS be amended by data and procedures also for the determination of the two **local-regional magnitude standards** ML and mb\_Lg.

3.) Comparing the results of the exercise with those derived by applying your current procedures of magnitude measurements to the same reference waveform data set will give you and your institution a clear understanding of the extent to which the new measurement standards yield results that agree or differ from your own results and to understand the reasons for possible differences.

4.) In this context there is an urgent need that stations and agencies which contribute parameter data to the International Seismological Centre (ISC) and the US National Earthquake Information Center (NEIC) provide an authoritative up-to-date **Documentation of station/agency magnitude procedures**. For your attention and easy response the related questions have been added as Annex 1 to this Information Sheet.

5.) **Note:** Should your agency not intend to introduce the recommended international standards in the future but to continue reporting your agency-specific *different* amplitude-magnitude data to the international data centres, then they need to be “flagged” by an agency-specific nomenclature. This permits data users to consult your documentation of station/agency magnitude procedures, to understand and account for related differences to the international standards and to decide about the suitability for your amplitude, period and magnitude data for their specific task.

6.) In the case that your institution uses some automatic procedures you should document how they work, e.g.:

- what type of original record data you have, their bandwidth and frequency range, whether displacement-proportional or velocity-proportional;
- which component and wave types are used for magnitude measurement;
- what type of filter (or none) is applied before amplitude, period and magnitude measurements are made;
- definition of time-window within which measurement is made, how the record amplitudes and periods are measured, which magnitude calibration functions are used, etc.).

7.) The current IS 3.4 provides reference data only for determining regional ( $M_s$ \_BB) and teleseismic magnitudes ( $m_b$ ,  $mB$ \_BB,  $M_s$ \_20 and  $M_s$ :BB) and related amplitudes, periods and measurement times. IS 3.4 will be amended in the course of 2012 by some more reference data and instructions for determining standard ML and  $m_b$ \_Lg. Also recommendations for using analysis software other than SEISAN may be added in future, provided that these analysis tools permit data filtering and presentation of measured amplitudes, periods, measurement times and magnitudes in a way that is compatible with the standard recommendations.

## 2. Data and software to be used and to be reported

In order to get an objective and reproducible comparison of IASPEI standard magnitudes with your institutional magnitudes both have to be measured on identical digital records.

With the exception of ML, all other magnitude standards are based on vertical-component recordings only. Therefore, we provide you in this first version of IS 3.4 only with single Z-component unfiltered STS-2 broadband velocity records, sampled at 20 Hz. These data will be complemented in 2012 by some horizontal component waveform files for ML determination. The records cover the whole wave train from the first P onset to the later part of the surface-wave group (respectively Sg-Lg group when ML and  $m_b$ \_Lg have to be determined).

The vertical component reference records have been made in a wide distance range from  $2^\circ$  to  $167^\circ$  from earthquakes with magnitudes between 4.7 to 8.5 (**Figure 1**). This allows you to check, whether differences between results of IASPEI standard procedures and your institutional procedures depend on distance and/or earthquake size.

**Annex 1** lists all reference event records, sorted according to epicentral distance, giving besides the record file name also the source region, hypocentral coordinates, epicentral distance of the recording station and the magnitude calibration value Q according to this distance and the source depth for the considered event.

Calibration values Q are given in the reference event list of **Annex 1** only for those magnitudes which can be determined for the given source depth and record distance. According to the recommended standards, no Q values are given for  $m_b$ ,  $mB$ \_BB and  $M_s$ \_20 at record distances less than  $20^\circ$  (then only for  $M_s$ \_BB), for  $m_b$  and  $mB$ \_BB at distances  $> 100^\circ$  and for  $M_s$ \_20 and  $M_s$ \_BB for earthquakes deeper than 60 km.

Further, the list contains columns for entering your measurements of the amplitude and periods used for calculation of the magnitude as well as of the time at which amplitude and period have been measured.

3

with the SEISAN manual, an introduction to exercises and to data from either the ftp site of the Institute of Geosciences of the University of Bergen, Norway (<http://www.uib.no/rg/geodyn/artikler/2010/02/software>) or directly via hyperlink **seisan** from the summary list of *Download Programs & Files* (see **Overview** of contents on the NMSOP-2 front page). Additional information can also be found in Havskov and Ottemöller (2010), and Havskov et al. (2011).

Different from the IASPEI Standard Format (ISF), all magnitude names in SEISAN - and in most other analysis software - still comprise only two letters. Yet, with the exception of Mw and duration/coda magnitude Mc, SEISAN calculates only IASPEI standard magnitudes. Yet, the calculation of mb\_Lg is not yet implemented although related amplitude measurements can be made. SEISAN mb is identical with the mb standard, provided that you measure the maximum amplitude in the whole P-wave group; the same applies to mB, which stands for standard mB\_BB. Further, SEISAN Ms means Ms\_20 and MS means Ms\_BB.

The measured amplitudes will be stored in the SEISAN event analysis files according to the unique IASPEI standard amplitude-phase names (see above and Table 1 below).

For measuring amplitudes and periods proceed as follow:

- 1.) SEISAN needs subdirectories for all years and months for which reference events are available. These subdirectories are stored in directories REA (S files) and WAV (waveform data), which are in turn stored in the basic directory (in general TEST\_). Type in the WOR (work) directory the command **makerea** and answer the questions. Answer GO AHEAD with Y (yes). New subdirectories are then created without changing already existing subdirectories.
- 2.) Load the magnitude reference event files into SEISAN with the commands **mulplt**, and **Regis**. Then you will be asked whether the event was local, regional or distant. You answer accordingly with either L, R or D and give your Operator Code (up to 4 letters).

The required vertical component broadband waveform files (and additional horizontal component waveform file for ML determination; to be specified in the later update of IS 3.4) can be downloaded via hyperlink from the folder **reference\_events** in the list of *Download Programs & Files* (see **Overview** on the NMSOP-2 front page). Therein you find the following tar-subfolders:

**ref\_evt\_00\_05.tar.gz** contains the waveform data files for the years 2000-2005;

**ref\_evt\_06\_09.tar.gz** those for 2006-2009 and

**ref\_evt\_94\_99.tar.gz** those for 1994-1999.

The reference events were recorded at station CLL in Germany. Note that two different digitizers were used, with the change occurring on 2 February 2007. The required response data files for SEISAN you find also in the folder **reference\_events**:

CLL\_BH\_Z.1993-04-13-000\_SEI and

CLL\_BH\_Z.2007-02-07-000\_SEI, respectively.

These files have to be loaded into the CAL directory.

- 3.) After this is done, load a specific event record file with **eev** yyyymmddhh. SEISAN then creates a line with running number, day, month, year, beginning of the time

window of the event record file and a question mark. After ? you may write the following **commands**:

- **po** for plot the seismogram (without further questions);
- **e** for read/edit the s file;
- **update** for saving the s file;
- **q** for finishing the evv.

In earlier versions SEISAN writes after the **po** command “aux station code not empty, use a station code ?”. Answer with any letter, but not with blank. In the new SEISAN version you can type ENTER. Then the requested complete seismogram will appear. Click on Menu and then - on the appearing command line - the “boxes” (buttons) for either WA (for Wood Anderson), mb, mB, Ms, or MS for which you wish to measure the amplitudes, periods and the amplitude-phase times. For ML, mb or Ms determination the respectively filtered record will then appear. For mB or MS you work on the instrument corrected unfiltered velocity broadband record.

- 4.) First choose the time resolution of the record so that the whole event record is present on the screen, including both the earlier body waves and the later surface waves with their usually (in the case of crustal earthquakes) much larger amplitudes and the longer and dispersive periods.
- 5.) For measuring mb or mB, increase the time resolutions by setting markers to cut the whole P-wave group out of the record. P usually has its largest amplitude between the first onsets of P and PP within the first minute (maybe including depth phases pP and/or sP). However, in the case of very great earthquakes ( $M_w > 8$ ) the rupture duration may last even for several (up to about 10) minutes and you may find the P-wave maximum only more than one min. after the first P-wave onset. In the case of ML and mb\_Lg measurement (which will be added in a later version of this exercise) increase the time resolution by cutting out the Sg-Lg group.
- 6.) Mark with the cursor the highest peak and deepest adjacent trough position and press at each marker position the letter **a**. Then the program will automatically measure the respective displacement or velocity amplitude, as well as the period and measurement time and write these parameter values into the **s(single)-file**. As measurement time the program takes the position of a vertical marker line which appears at the picked deepest trough position. This differs in time by about  $\pm$  a quarter of a period from the amplitude-phase arrival-times according to the IASPEI standard, which is measured as the time of the zero-crossing between the peak and adjacent-trough from which the amplitudes are measured. But this is close enough.
- 7.) This interactive measurement procedure is preferred for our exercise and reference event task. It will train both your own assessment of the different record appearance as well as of the specifics of the SEISAN program in relation to the recommended IASPEI standards for magnitude measurements. However, SEISAN allows also to measure automatically Amax (or Vmax) and T within the whole time window visible on the screen when you set the cursor somewhere near to the maximum of the whole local event train or of the teleseismic P-wave time train and press the capital letter **A**. This works fine, however, only in the case of good signal-to-noise ratio.
- 8.) For Ms (Ms\_20) and MS (Ms\_BB) proceed in the same way after selecting the Rayleigh (LR) surface-wave part of the record and then, with a higher time resolution, the time window around the LR maximum.

In Table 1 we show an example of the S file (with the original name 14-0926-00D.S200111) into which SEISAN has written the results of the amplitude (A) and period (T) measurements for the event 2001 1114 926 0.0D. Note that SEISAN stores the measured amplitudes with the correct IASPEI standard amplitude nomenclature in accordance with the IASPEI Standard Format (ISF), which is used at the international seismological data centers such as the ISC and NEIC. This amplitude nomenclature allows to associate the measured amplitudes unambiguously with the respective standard magnitudes. Therefore, standard amplitude measurements have in future to be reported to the international data centers in this format.

Table 2 will be added later, giving a similar data example for IAML, IAmb\_Lg, and IVMs\_BB (measured down to epicentral distance of 2°).

**Table 1** Plot of the amplitude-period data measured with SEISAN for 4 different telesismic IASPEI standard magnitudes from one reference event record.

```

```

- 9.) Insert for the analyzed events the measured displacement amplitudes (and periods, were required) as well as the values in **Annex 1** for QP and QL into the following formulas:

$$mb = \log_{10}(A/T) + QP - 3.0, \text{ respectively}$$

$$Ms_{20} = \log_{10}(A/T) + QL - 3.0,$$

and the related measured velocity amplitudes into the formulas:

$$mB_{BB} = \log_{10}(V_{\max}/2\pi) + QP - 3.0, \text{ respectively}$$

$$Ms_{BB} = \log_{10}(V_{\max}/2\pi) + QL - 3.0$$

and calculate the respective magnitudes with a spread sheet or pocket calculator. The -3.0 is required, since SEISAN and most other currently used analysis programs measure amplitudes in nm, whereas the classical calibration values and formulas for body and surface-waves were based on amplitude measurements in  $\mu\text{m}$ .

- 10.) Finally, insert the measured amplitudes, periods, measurement times and the calculated magnitudes into the respective empty (hyphen-less) column-lines of the reference event list (**Annex 1**). **txt**, **xls** and **doc** file versions of the tables can be

downloaded via the folder **reference\_events** from the listing of *Download Programs & Files* (see **Overview** on the NMSOP-2 front page)

**For clarification:** When you pick the onset times on records of several seismic stations, either local, regional or globally distributed ones, and locate first the seismic event yourself with SEISAN then the respective source parameters and epicentral distances are automatically calculated and stored in the respective SEISAN event file, thus enabling direct calculation of the magnitudes from the measured amplitudes and periods..

In our case, however, we have provided you only with one single component record. From this SEISAN can not calculate the source parameters and required Q values, unless you type yourself the event coordinates and station distance into the respective SEISAN event file. This, however, might be a potential source for typos and thus wrong results. Therefore, we request you to calculate for this comparative exercise the magnitudes yourself.

This detour, however, you will not encounter in the routine use of SEISAN for event location and magnitude determination using local, regional or global network records.

#### 4. How to measure and report your institutional magnitudes?

If you use at your station/network either an interactive or an automatic program for seismogram analysis and parameter determination please let us know the name and version (year) of the program.

If you determine at your station/network centre magnitudes with an interactive analysis program then please load the reference event files into your program, and the 4 required response parameters for the events files. Then proceed by measuring the amplitude and period as you usually do, calculate the related body-wave and/or surface-wave magnitude according to your respective formulas and report it/them to us in the last but one column of the list in **Annex 3**.

If you avail only of a fully automatic program for magnitude determination then you should check whether you can load the reference event files, together with the response parameters and pre-determined epicentral distance and source depth data into the program and get it run off-line for determining the magnitude value(s) according to the program's procedure. Report to us then these values with your common magnitude symbols in the last but one column (second from the right).

If your center operates a hybrid automatic program which also allows working in an interactive mode for a more detailed expert-controlled final data analysis (like e.g. SeisCompP) then load the reference event waveforms and the 4 required response parameters for the events files into the program and use the interactive program mode for measuring amplitudes and periods and determine the magnitudes according to your common station/agency procedure of data analysis. Report these results in the last but one column.

If your agency had determined for any of the reference events already earlier magnitudes - interactively or automatically - using your own station or network data and procedures, then please report these values and the magnitude type to us in the last column. Indicate which parameter data were determined interactively (int) or automatically (aut). Data provided in the last column will permit us to assess how the magnitudes based on your own data relate to

both the NEIC magnitudes and the single station standard reference magnitudes determined by Dr. S. Wendt for CLL station.

## 5. To whom you may address related questions and submit your station/agency analysis results and questionnaire answers?

In the case of any questions related to the SEISAN analysis software, the use of the reference data set, results or encountered problems you may address them to

Dr. Siegfried Wendt at the Observatory Collm, University of Leipzig  
E-mail: [obssw@hpwork30.collm.uni-leipzig.de](mailto:obssw@hpwork30.collm.uni-leipzig.de) or [wendt@rz.uni-leipzig.de](mailto:wendt@rz.uni-leipzig.de).

Your analysis results (filled-in list in **Annex 1**) and answers to the requested documentation of your station/agency magnitude procedures (**Annex 2**) should be sent to both Dr. Wendt and Prof. Dr. Peter Bormann, E-mail: [pb65@gmx.net](mailto:pb65@gmx.net).

We will analyze your response, feedback with you and pass the final outcome for further consideration to the IASPEI WG on Magnitude measurement, to the ISC and the NEIC. Good feedback and interesting results may justify to envisage a joint journal publication. Thanks in advance for your valuable co-operation.

## Acknowledgment

We thank Dr. James W. Dewey, USGS, and Prof. Lars Ottemöller, University of Bergen, for reviewing this contribution and their valuable hints, which will also be considered in future upgrading of the IS.

## Annex 1

## Reference event list

Below find a reference event list for the analysis of IASPEI standard magnitudes mb, mB\_BB, Ms\_20 and Ms\_BB in comparison with your station/agency procedures and types of magnitude. Note that no measurements and data entries are required in column-lines with – . The hyphen indicates that at the given event distance and/or source depth the respective magnitude is not defined. No calibration values QP or QL are given in this case. If, however, your station/center has determined a magnitude for this event, because your station/network recorded this event at a suitable distance for magnitude determination, then please give the respective value and type of magnitude in the last column.

The reference list has been printed below as a table in a compressed form with rather small letters. Magnify it for reading, plotting, filling in your answers and sending them back to the authors. Alternatively you may use the respective ASCII files: **ref\_evt\_1.text** and **ref\_evt\_2.txt** or the Exel file **ref\_evt.xls** in the directory [reference\\_events](#) (see in **Overview** on the NMSOP-2 front page for listing of *Download programs and files*).

## Annex 2

**DOCUMENTATION OF STATION/AGENCY MAGNITUDE PROCEDURES**

(Copied from the SUMMARY OF IASPEI MAGNITUDE WORKING GROUP RECOMMENDATIONS ON DETERMINING EARTHQUAKE MAGNITUDES FROM DIGITAL DATA, updated version 2011; see [http://www.iaspei.org/commissions/CSOI/Summary\\_WG-Recommendations\\_20110909.pdf](http://www.iaspei.org/commissions/CSOI/Summary_WG-Recommendations_20110909.pdf))

Documentation of procedures for amplitude/period based magnitudes by seismographic stations/analysis centers should generally address the following points:

1. Phase-type from which the amplitude measurement is made.
2. Units of the reported amplitude. Specify if amplitudes are reported in units of trace-amplitude motion instead of ground motion.
3. Time-window in which the amplitude measurement is made.
  - a. For example, a flexible time-interval between the P onset and the PP onset or a fixed time window after the first P onset (e.g. 5 s, 10s or other).
  - b. For example, the time-interval spanned by waves having group-velocities between 3.2 and 3.8 km/s.
4. Amplitude-response, filter characteristics, or transfer-function of the seismograph or simulated seismograph through which the amplitude measurement is made.
5. Orientation of seismograph (horizontal or vertical) from which the measurement is made.
6. Details of measuring amplitude
  - a. For example, does the amplitude correspond to  $0.5 \times (\text{peak-to-trough amplitude})$ , where “peak-to-trough amplitude” corresponds to difference between a maximum positive excursion and a maximum negative excursion of the trace, or is the amplitude instead measured as the maximum absolute excursion from the “zero” position of the seismograph trace?
  - b. For example, if the amplitude corresponds to  $0.5 \times (\text{peak-to-trough amplitude})$ , are the “peak” and “trough” respectively the absolute maximum and absolute minimum values of the entire wave-group, or are they the adjacent peak and trough corresponding to the maximum trace excursion that is associated with a single zero-crossing?
  - c. For example, are displacement amplitude(A) and period(T) measured at the time of maximum A or at the time of the maximum of the quotient (A/T)?
  - d. For example, any way in which station/agency procedure differs from the corresponding IASPEI standard procedure.

7. Details of measuring period, for example, is it the time between the neighboring peaks, respectively troughs or twice the time span measured between the largest peak and adjacent trough at which the double amplitude has been measured.
8. To what part of a phase the amplitude-measurement time refers. For example, is the amplitude-measurement time the time of the zero-crossing associated with a peak-to-adjacent trough measurement or is it the time of an absolute maximum or absolute minimum?
9. The equations that are used for calculating particular types of magnitudes
  - a. Specify if distance is measured as epicentral distance or hypocentral distance.
  - b. Specify the distance range for which the equation is applied.
  - c. Specify restrictions on hypocentral focal-depth, if any.
10. Other restrictions on the calculation of the magnitude
  - a. For example, must signal-amplitude satisfy a signal-to-noise ratio criterion?
  - b. For example, is the magnitude measured only for earthquakes of a certain size, as defined by an independent measure of earthquake size?
11. Any way in which the magnitude procedure departs from an IASPEI standard procedure if the procedure is intended to produce the IASPEI standard magnitude.
  - a. For example, if measurements are made over a somewhat different distance or depth range than specified in the IASPEI procedure.
  - b. For example, if non-standard filtering is applied in some situations in which the non-standard filtering **is not expected to affect the magnitude** (e.g., when measuring magnitudes for very small events for which standard-filtering would produce records of too small signal-to-noise ratio). Please specify.
12. How data are averaged for a network average.
  - a. For example, is the network average a simple arithmetic mean, a trimmed mean, the median value, or some other average?
  - b. If, as for example might be the case for ML, data from each of two horizontal components at a single station are used, are data from each component treated as a separate observation in the network average, or are the two components first averaged into a station magnitude, which is then treated as a single observation in the network average?

For some magnitude types (e.g., coda-based magnitudes) the procedures to be documented will have to be substantially altered from the preceding to better reflect the measurements that are critical to those magnitude-types, but the level of detail should be analogous to what is proposed above for amplitude/period based magnitudes.

Please insert your answers to the above questions in color for easier recognition and send them back to

## 1 Introduction

Although  $M_e$  and  $M_w$  are magnitudes that describe the size of an earthquake, they are not equivalent.  $M_e$ , being derived from velocity power spectra, is a measure of the radiated energy in the form of seismic waves and, thus, of the seismic potential for damage to anthropogenic structures.  $M_w$ , being derived from the low-frequency asymptote of displacement spectra, is physically related to the final static displacement of an earthquake. As seen in the  $M_e$ - $M_w$  plot of global earthquakes from 1987-2009 (Figure 1), for any given  $M_w$ , the corresponding  $M_e$  may vary by as much as an entire magnitude unit and vice versa.

**Figure 1**  $M_e$ - $M_w$  for global shallow (depth < 70 km) earthquakes with magnitude greater than about 5.5.  $M_e$  are taken from the USGS/NEIC source parameters catalog which has included direct computation of radiated energy  $E_s$  since 1987.  $M_w$  are taken from the global Centroid Moment Tensor (gCMT) catalog. The least-squares linear regression with an assumed slope of one (solid line) yields a global average apparent stress for earthquakes of 0.5 MPa. But the 95% spread about the mean (indicated by the dashed lines) shows that for any given  $M_w$ ,  $M_e$  scatters about one-half a magnitude unit above and below the mean value, with some outliers up to one magnitude unit. No single empirical formula can adequately represent such a spread.

Events with anomalously high  $M_e$  relative to  $M_w$  should have greater potential for seismic damage than those earthquakes with relatively low  $M_e$ . Indeed, Choy et al. (2001) [see also Table 3.2 in Chapter 3 of the first edition of the NMSOP (Bormann et al., 2002)] first demonstrated this dramatically by comparing the significantly different macroseismic effects of two earthquakes in the same epicentral region that had nearly the same  $M_w$  but had  $M_e$ 's differing by 1.0 unit. The objective of this Information Sheet is to demonstrate that the apparent scatter in  $M_e$ - $M_w$  is non-random. Subsets of earthquakes chosen on the basis of a specific tectonic setting, seismic region and focal-mechanism type occupy specific sectors of the  $M_e$ - $M_w$  plot. Moreover, the stress conditions unique to specific sectors can be incorporated into a model of fault maturity. Rather than be daunted by the large spread in  $M_e$ - $M_w$ , methods of estimating tsunami and seismic hazards can be enhanced by exploiting the patterns of stress conditions available from  $M_e$ - $M_w$  data.

## 2 Ways to measure the amount of energy released per unit moment

There are several equivalent ways to represent the radiated energy to moment ratio of an earthquake:

- Apparent stress,  $\tau_a = \mu E_S / M_0$
- Scaled energy,  $E_S / M_0$
- Slowness parameter,  $\Theta = \log( E_S / M_0 )$
- Differential magnitude,  $\Delta M = M_e - M_w$

The advantage of using apparent stress  $\tau_a$  (where  $\mu$  is rigidity) is that it can be related to other stresses associated with rupture (Wyss and Brune, 1968). Although the relationship between apparent stress and stress drop is model dependent, larger apparent stress generally implies larger stress drop. The dimensionless ratio  $E_S/M_0$ , often called scaled energy (Kanamori and Heaton, 2000), is independent of  $\mu$ , but is slightly cumbersome to enunciate as it typically ranges from  $10^{-4}$ - $10^{-6}$  for teleseismically analyzable earthquakes. Taking the log of the scaled energy yields a more manageable number which Newman and Okal (1998) call the slowness parameter  $\Theta$ . Another equivalent method presented here is differential magnitude  $\Delta M$ , defined as the difference between the energy and moment magnitudes,  $M_e$  and  $M_w$ ,

$$\Delta M = M_e - M_w \quad (1)$$

From the equations for  $M_e$  and  $M_w$ , we can derive useful relationships between the various representations. We use  $M_w = (2/3)(\log M_0 - 9.1)$  and  $M_e = (2/3)(\log E_S - 4.4)$ . These forms of  $M_w$  and  $M_e$ , first proposed in Chapter 3 of the NMSOP (Bormann et al., 2002) and accepted by IASPEI (2005) as standard formulas, avoid occasional rounding errors up to 0.1 m.u. which can occur in the formulas originally published by Hanks and Kanamori (1979) for  $M_w$  and by Choy and Boatwright (1995) for  $M_e$ .

Between differential magnitude and scaled energy we have

$$\Delta M = (2/3) [\log ( E_S/M_0 ) + 4.7] \quad (2)$$

Between differential magnitude and  $\Theta$  :

$$\Delta M = (2/3) [\Theta + 4.7]. \quad (3)$$

An important relationship between  $M_e$ ,  $M_0$ , and  $\tau_a$  was recognized [eq. 11 of Choy and Boatwright (1995)] as  $M_e = (2/3) [\log M_0 + \log(\tau_a/\mu)] - 3.2$ , which can also be written as

$$M_e = (2/3) [\log M_0 + \log(\tau_a/\mu) - 4.8], \quad (4)$$

The constant 4.8 corresponds to the constant in the classical Gutenberg-Richter relationship  $\log E_s = 4.8 + 1.5 M_s$ . However, the U. S. Geological Survey's National Earthquake Information Center accepted in its Monthly Listings of the Preliminary Determination of Epicenters July 1995 the new Choy and Boatwright (1995) constant 4.4, derived from the best fitting slope of 1.5 through directly measured  $\log E_s$  data vs.  $M_s$  [see Figure 4 and eq. 6 in Choy and Boatwright (1995)]. Replacing in eq. (4) the constant 4.8 by 4.4 yields

$$M_e = (2/3) [\log M_0 + \log(\tau_a/\mu) - 4.4], \quad (5)$$

and when introducing therein the IASPEI (2005) standard formula  $M_w = (2/3) (\log M_0 - 9.1)$

$$M_e = M_w + (2/3) [\log(\tau_a/\mu) + 4.7]. \quad (6)$$

Equivalent relationships between  $M_e$ ,  $M_w$  and apparent stress were published by Bormann and Di Giacomo (2011).

The relationship between differential magnitude and apparent stress is then:

$$\Delta M = (2/3) [\log(\tau_a/\mu) + 4.7]. \quad (7)$$

In the  $M_e$ - $M_w$  plots that follow,  $M_e$ - $M_w$  data pairs for earthquakes based on tectonic setting and focal mechanism are fit by a least squares regression to a line with slope 1,

$$M_e = M_w + c.$$

The apparent stress is related to the constant  $c$  through eq. (6). Note that in order to compute average  $\tau_a$  we use  $\mu$  appropriate to the source depth for each event.

### 3 Identifying events that radiate exceptionally high energy

To identify an earthquake as having radiated exceptionally high energy relative to its moment, we adopt the criterion of Choy and Kirby (2004) that  $\tau_a > 1$  MPa or, equivalently,  $\Delta M$  greater than about 0.0 (i.e., whenever  $M_e \geq M_w$ ). This criterion was derived from their global investigation of subduction-zone earthquakes, in which they found that normal-fault earthquakes occurring in high-deformation regimes were always associated with exceptionally higher energy release than other normal-fault earthquakes. Characteristics of high-deformation regimes include sharp changes in slab geometry, colliding slabs and oblique convergence at a subducting plate boundary. Less than 20% of all normal-fault earthquakes are energetic events. Figures 2 and 3 show that these high energy events occupy narrow sectors in the  $M_e$ - $M_w$  plot.

**Figure 2** Me-Mw of deeper (  $35 \text{ km} < h < 70 \text{ km}$  ) normal-fault events (solid black circles) that occur at a sharp change in slab geometry or in the deformation zone of converging but oppositely oriented slabs. These events have an average apparent stress nearly 4 times higher than the global population (gray circles).

**Figure 3** Me-Mw of shallower ( $h < 35 \text{ km}$ ) events (solid black circles) that occur intraslab and landward of the trench axis at subduction boundaries where plate convergence is oblique to the fabric of the seafloor. These events have an average apparent stress more than 3 times higher than that of the global data (gray circles).

The subset of intraoceanic strike-slip events occupies a unique sector of the Me-Mw plot. Although they constitute only 5% of the global shallow earthquakes, they have the highest average  $\tau_a$  of any earthquake subset. Figure 4 plots Me-Mw for the set of strike-slip

earthquakes in the oceans (excluding subduction zones). The average  $\tau_a$  for oceanic strike-slip earthquakes is about 18 times higher than the global average. At first glance this seems contrary to the original simple tenets of plate tectonic tenets, wherein strike-slip earthquakes in the oceans are thought to be dominated by the simple slippage along transform faults of weak material. Choy and McGarr (2002), however, have shown that the actual situation is far different: more oceanic strike-slip earthquakes occur in the vicinity (less than a couple of degrees) of transforms than on the transforms themselves. Far from being a simple plate boundary, ridge-transform systems are apparently the site plate boundary reorganization. The intraplate earthquakes are the consequence of fracture on new faults that result from locally intense deformation. Even the events that do occur on transforms either (1) have nodal planes not coincident with the strike of the transform; (2) occur on short-offset transform segments; or (3) occur on the inside corners of the ridge-transform intersect. These conditions also require the fracture of fresh rock or newly formed faults as the local plate boundary evolves. Moreover, the depths of nucleation of these earthquakes have been shown from broadband seismogram modeling (Choy and McGarr, 2002; Abercrombie and Ekström, 2001) to be between 5-25 km, well within the oceanic mantle. Thus, the higher strength of oceanic vs. continental mantle also contributes to the high energy release.

**Figure 4** Me vs. Mw for the subset of 135 intraoceanic strike-slip earthquakes (dark solid circles) occurring on or near transform faults or intraplate compared to that of global earthquakes (gray circles).

#### 4 Identifying events that radiate exceptionally low energy

To characterize an earthquake as being enervated, that is, having radiated exceptionally low energy, we adopt the criterion of Newman and Okal (1998) that its slowness parameter  $\Theta < -5.5$ . This is equivalent to a differential magnitude  $\Delta M$  less than about -0.50. Figure 5 plots  $\Delta M$  vs.  $M_W$  for all thrust earthquakes that occurred in subduction environments. The global average  $\Delta M$  is -0.36. Earthquakes which radiate anomalously low energy fall below the line  $\Delta M = -0.5$  (Quadrants III and IV). Quadrant IV contains the class of enervated earthquakes

with  $M_w > 7.5$ . Earthquakes in this class have been called “slow” earthquakes because of their abnormally long source durations and anomalously low radiated energy relative to seismic moment (Newman and Okal, 1998). There are only 22 such events, but virtually all of them have generated tsunamis. It should be noted that in quadrant III are another 257 earthquakes that also radiated anomalously low energy but with smaller magnitudes,  $M_w$ 's  $< 7.5$ . The earthquakes in quadrants III and IV do not necessarily occur in the same seismic regions. Nor is there any obvious spatial correlation of the smaller enervated events with locations of notable slow tsunami earthquakes. This may be because patterns have not yet developed in the relatively short time for which accurate radiated energies have been available. Whether there are other tectonic, geophysical or geological connections between the large tsunamigenic earthquakes and the smaller enervated earthquakes is not known at this time and requires further research. Finally, we note that the combined population of mid-energy and enervated earthquakes (i.e., quadrants II, III and IV with  $\Delta M < 0.0$ ) are predominantly interface thrust events for which the average  $\tau_a$  a little less than 0.3 MPa. The class of subduction-interface thrust events, thus, has the lowest  $\tau_a$  of any subset of earthquakes based on tectonic setting and focal mechanism.

**Figure 5**  $\Delta M$  vs.  $M_w$  for 1306 thrust earthquakes occurring in subduction regions from 1987-2009. The global average  $\Delta M$  is -0.36 (short dashed line). Earthquakes radiating anomalously low energy fall below the line  $\Delta M = -0.5$  (lower dashed line). Earthquakes radiating anomalously high energy fall above the line  $\Delta M = 0.0$ .

Note that in quadrant I there are 163 subduction-thrust earthquakes with  $\Delta M > 0.0$  which, by the criterion of our previous section, are considered to be high energy events. These

earthquakes comprise only 12% of the subduction-thrust population. They are most often found in subduction regions involving complex plate deformation (Choy and Kirby, 2009). These region types include: marine collision zones involving seamount chains or fracture zones, submerged continent-continent collisions, colliding slabs, regions of multiple plate interactions, and slab distortions. Many of these events may be intraslab based on their greater depths (compared to shallower events that are presumed to be on the subduction interface) as well as their focal mechanisms whose nodal planes are not aligned with the slab interface.

## 5 Development of a fault maturity model

The first three rows of Table 1 below summarize in ascending order the average apparent stresses of earthquake populations we have described, their respective tectonic settings and their dominant focal mechanism type. If we define fault maturity as the amount of offset accumulated by a fault, then we see that fault maturity is inversely related to average apparent stress. At one extreme, the least mature faults would have had little to no previously accumulated displacement and, hence, they should have maximum fault roughness. An example would be strike-slip earthquakes in oceanic lithosphere, which have the highest average  $\tau_a$  of any class of earthquake. The majority of these earthquakes are either intraplate or they occur on short transforms or the inside corners of ridge-transforms (where fresh material is being ruptured). At the other extreme, the most mature faults would have large total displacements. This is typified by subduction-thrust earthquakes occurring on the frictional contact between overriding and subducting plates. Thus, the level of  $\tau_a$  appears to be related to the degree to which lithosphere can sustain strain accumulation before rupturing.

**Table 1** The inverse relationship between average  $\tau_a$  ( $\langle \tau_a \rangle$ ) of a tectonic setting and fault maturity.

| Fault Maturity               | <div> <div>High</div> <div>Low</div> </div>                                                                            |                                                     |                                                       |                                                           |              |

Although the range of apparent stress for teleseismically analyzable earthquakes is a continuum from less than 0.05 MPa up to 250 MPa, the outlier populations of earthquakes that radiate anomalously low or high amounts of energy are easily identifiable. The criteria stated in terms of apparent stress, slowness parameter  $\Theta$  and differential magnitude  $\Delta M$  are summarized in Table 2. These outlier populations have significant implications for tsunami

and seismic hazards evaluation, respectively. Slow earthquakes associated with transoceanic tsunamis have been characterized as having abnormally long source durations and anomalously low radiated seismic energy. On the other hand, the  $M_w$  of highly energetic earthquakes might belie the actual potential for damage from shaking. Figure 6 highlights three recent events (red stars) which inflicted considerable destruction or generated macroseismic effects. The  $\Delta M$ 's of the Haiti 2010, Darfield, New Zealand 2010 and Christchurch, New Zealand 2011 earthquakes range from 0.4 to 0.7. From these  $\Delta M$  values we would rank their faults as immature and capable of higher seismic potential than their  $M_w$  alone would imply.

**Table 2** Approximate relationship between apparent stress  $\tau_a$ , slowness  $\Theta$ , and differential magnitude  $\Delta M$ . The relations are approximate as the value of shear modulus  $\mu$  is a function of depth and earth structure. Thus,  $\tau_a$  is influenced more by focal depth than  $\Theta$  and  $\Delta M$ .

|                        | Slow tsunami earthquake | Energized earthquake | Global average    | High energy            |
|------------------------|-------------------------|----------------------|-------------------|------------------------|
| $\tau_a$               | $< 0.1 \text{ MPa}$     | $< 0.1 \text{ MPa}$  | $0.5 \text{ MPa}$ | $\geq 1.0 \text{ MPa}$ |
| $\Theta$               | $< -5.5, M_w \geq 7.5$  | $< -5.5, M_w < 7.5$  | $-4.9$            | $\geq -4.6$            |
| $\Delta M (M_e - M_w)$ | $< -0.5, M_w \geq 7.5$  | $< -0.5, M_w < 7.5$  | $-0.2$            | $\geq 0.0$             |

**Figure 6** The red stars highlight some recent damaging earthquakes with  $M_e \gg M_w$ : the Haiti 2010, Darfield, New Zealand 2010 and Christchurch, New Zealand 2011 earthquakes. For comparison, global earthquake  $M_e$ - $M_w$  data are plotted as gray open circles and black closed circles show the subset of oceanic strike-slip earthquakes which are categorized as immature.

## 6 Summary

Modern magnitudes  $M_w$  and  $M_e$  are direct measures of radiated energy and seismic moment, respectively. The amount of energy radiated per unit of seismic moment, representable in several ways such as differential magnitude  $\Delta M$  and apparent stress  $\tau_a$ , can be interpreted as an indicator of stress conditions in the lithosphere. Given the observed scatter in  $M_e$ - $M_w$  plots for the global earthquake population, no single empirical formula can accurately predict  $M_w$  from  $M_e$ . However, the  $M_w$  and  $M_e$  for subsets of earthquakes chosen on the basis of a specific tectonic setting, seismic region and focal-mechanism type occupy specific sectors of the  $M_e$ - $M_w$  plot. These patterns can be exploited to identify conditions of elevated seismic hazard, to identify conditions of elevated tsunami potential, and to be related to a model of fault maturity.

## 1 Introduction

One of the most fundamental parameters for describing an earthquake is radiated seismic energy. In theory, its computation simply requires an integration of radiated energy flux in velocity-squared seismograms. In practice, energy has historically almost always been estimated with empirical formulas. The empirical approach dominated for two major reasons. First, until the 1980's most seismic data were analog, a format which was not amenable to spectral processing on a routine basis. Second, an accurate estimate of radiated energy requires the analysis of spectral information both above and below the corner frequency of an earthquake, about which energy density is most strongly peaked.

Prior to the worldwide deployment of broadband seismometers, which started in the 1970's, most seismograms were recorded by conventional seismographs with narrowly peaked instrument responses. The difficulties in processing analog data were thus compounded by the limitations in retrieving reliable spectral information over a broad bandwidth. Fortunately, theoretical and technological impediments to the direct computation of radiated energy have been removed. The requisite spectral bandwidth is now recorded digitally by a number of seismograph networks and arrays with broadband capability, and frequency-dependent corrections for source mechanism and wave propagation are better understood now than at the time empirical formulas were first developed.

## 2 How is radiated seismic energy measured?

### 2.1 Method

The method described below for estimating the radiated seismic energy of teleseismic earthquakes is based on Boatwright and Choy (1986). Velocity-squared spectra of body waves are corrected for effects arising from source mechanism, depth phases, and propagation through the Earth.

For shallow earthquakes where the source functions of direct and surface-reflected body-wave arrivals may overlap in time, the radiated energy of a  $P$ -wave group (consisting of  $P$ ,  $pP$  and  $sP$ ) is related to the energy flux by

$$E_S^P = 4\pi \langle F^P \rangle^2 \left( \frac{R^P}{F^{gP}} \right)^2 \mathcal{E}_{gP}^* \quad (1)$$

where the  $P$ -wave energy flux,  $\mathcal{E}_{gP}^*$ , is the integral of the square of the ground velocity, taken over the duration of the body-wave arrival,

$$\mathcal{E}_{gP}^* = \rho\alpha \int_0^\infty \dot{u}(t)^2 dt \quad (2)$$

Here,  $\dot{u}$  is velocity, which must be corrected for frequency-dependent attenuation;  $\rho$  and  $\alpha$  are density and velocity at the receiver, respectively;  $\langle F^P \rangle^2$  is the mean-square radiation-pattern coefficient for  $P$  waves;  $R^P$  is the  $P$ -wave geometrical spreading factor;  $F^{gP}$  is the generalized radiation pattern coefficient for the  $P$ -wave group defined as

$$(F^{gP})^2 = (F^P)^2 + (\hat{P}P F^{pP})^2 + \frac{2\alpha q}{3\beta} (\hat{S}P F^{sP})^2 \quad (3)$$

where  $F^i$  are the radiation-pattern coefficients for  $i = P$ ,  $pP$ , and  $sP$ ;  $\hat{P}P$  and  $\hat{S}P$  are plane-wave reflection coefficients of  $pP$  and  $sP$  at the free surface, respectively, corrected for free-surface amplification; and  $q$  is 15.6, the ratio of  $S$ -wave energy to  $P$ -wave energy (Boatwright and Fletcher, 1984). The correction factors explicitly take into account our knowledge that the earthquake is a double-couple, that measurements of the waveforms are affected by interference from depth phases, and that energy is partitioned between  $P$  and  $S$  waves. For teleseismically recorded earthquakes, energy is radiated predominantly in the bandwidth 0.01 to about 5.0 Hz. The wide bandwidth requires a frequency-dependent attenuation correction (Cormier, 1982). The correction is easily realized in the frequency domain by using Parseval's theorem to transform Eq. (2),

$$\mathcal{E}_{gP}^* = \frac{\rho\alpha}{\pi} \int_0^\infty \dot{u}(\omega)^2 e^{\omega t_\alpha^*} d\omega \quad (4)$$

where  $t_\alpha^*$  is proportional to the integral over ray path of the imaginary part of complex slowness in an anelastic Earth. An appropriate operator, valid over the requisite broad bandwidth, is described by Choy and Cormier (1986) and shown in Figure 1. The  $t_\alpha^*$  of the  $P$ -wave operator ranges from 1.0 s at 0.1 Hz to 0.5 s at 2.0 Hz.

**Figure 1** Teleseismic  $t_{\alpha}^*$  derived by Choy and Cormier (1986) plotted as a function of frequency for a surface-focus source and a surface receiver at a distance of  $60^\circ$ . The split in the curve at frequencies higher than 0.3 Hz indicates the variation in regional  $t_{\alpha}^*$  expected for different receiver sites. In practice the mean of the two curves is used for the attenuation correction.

The numerical integration of Eq. (4) is limited to either the frequency at which signal falls below the noise level (typically at frequencies greater than 2.0-3.0 Hz) or to the Nyquist frequency. If this limiting or cutoff frequency,  $\omega_c$ , is greater than the corner frequency, the remainder of the velocity spectrum is approximated by a curve that falls off by  $\omega^{-1}$ . In practice, therefore, Eq. (4) consists of a numerical integral,  $N$ , truncated at  $\omega_c$ , and a residual integral,  $R$ , which approximates the remainder of the integral out to infinite frequency,

$$\mathcal{E}_{gp}^* = \rho \alpha N + \rho \alpha R \quad (5)$$

where, as shown in Boatwright and Choy (1986),

$$R = \frac{\omega_c}{\pi} \left[ \dot{u}_c(\omega_c) \right]^2 \quad (6)$$

in which  $\dot{u}_c$  is the attenuation-corrected value of velocity at  $\omega_c$ .

Although teleseismic  $SH$ - and  $SV$ -wave groups from shallow earthquakes can be analyzed through a straightforward extension of Eq. (1) as described in Boatwright and Choy (1986), shear waves suffer substantially more attenuation in propagation through the Earth than the  $P$  waves. The loss of seismic signal due to shear attenuation usually precludes retrieving useful spectral information for frequencies higher than about 0.2-0.3 Hz for all but the largest earthquakes. Thus, for the routine estimation of energy, it is more practical and more accurate to use only the  $P$ -wave group (Eqs. (1) and (4)). The formula for computing the total radiated energy when using the  $P$ -wave group alone is

$$E_s = (1 + q) E_s^P. \quad (7)$$

## 2.2 Data

Data used in the direct measurement of energy must satisfy three requirements. First, the implementation of Eq. (4) requires that the velocity data contain spectral information about, above and below the corner frequency of an earthquake. Because the corner frequency can vary from earthquake to earthquake depending on source size and rupture complexity, the bandwidth of the data must be sufficiently wide so that it will always cover the requisite range of frequencies above and below the corner frequency. For body waves from teleseismically recorded earthquakes, a spectral response that is flat to ground velocity between 0.01 Hz through 5.0 Hz is usually sufficient. The second requirement is that the duration of the time window extracted from a seismogram should correspond to the time interval over which the fault is dynamically rupturing. As shown by the examples in Figure 2, when broadband data are used, delimiting the time window is generally unequivocal regardless of the complexity of rupture or the size of the earthquake. The initial arrival of energy is obviously identified with the onset of the direct *P* wave. The radiation of energy becomes negligible when the amplitude of the velocity-squared signal decays to the level of the coda noise. The final requirement is that we use waveforms that are not complicated by triplications, diffractions or significant secondary phase arrivals. This restricts the usable distance range to stations within approximately 30°-90° of the epicenter. In addition, waveforms should not be used if the source duration of the *P*-wave group overlaps a significant secondary phase arrival. For example, this may occur when a very large earthquake generates a *P*-wave group with a duration of such length that it does not decay before the arrival of the *PP*-wave group.

**Figure 2 (Left)** Broadband displacement, velocity, and velocity-squared records for the large ( $M_s = 7.8$ ,  $M_e = 7.5$ ,  $M_w = 7.7$ ) Chilean earthquake of 3 March 1985. Rupture complexity, in the form of a tiny precursor and a number of sub-events, is typical for large earthquakes. **(Right)** Broadband displacement, velocity and velocity-squared records for an aftershock ( $m_b = 5.9$ ,  $M_e = 6.2$ ,  $M_w = 6.6$ ) to the Chilean earthquake that occurred 17 March 1985. The waveforms are less complex than those of the main shock. Despite the differences in rupture complexity, duration and amplitude, the time window over which energy arrives is unequivocal. In each part of the figure the arrows indicate when the velocity-squared amplitude has decreased to the level of the coda noise.

### 3 Development of an energy magnitude, $M_e$

In the Gutenberg-Richter formulation, an energy is constrained once magnitude is known through  $\log E_s = a + b M$  where  $a$  and  $b$  are constants. For surface-wave magnitude,  $M_s$ , the Gutenberg-Richter formula takes the form

$$\log E_s = 4.8 + 1.5 M_s \quad (8)$$

where  $E_s$  is in units of Joules (J). In the normal usage of Eq. (8), an energy is derived after an  $M_s$  is computed. However, it is now recognized that for very large earthquakes or very deep earthquakes, the single frequency used to compute  $M_s$  is not necessarily representative of the dimensions of the earthquake and, therefore, might not be representative of the radiated energy. Since radiated energy can now be computed directly, it is an independent parameter from which a unique magnitude can be defined. In Figure 3, the radiated energies for a set of 378 global shallow earthquakes from Choy and Boatwright (1995) are plotted against their magnitudes,  $M_s$ . The Gutenberg-Richter relationship is plotted as a dashed line in Figure 3. Assuming a  $b$ -value of 1.5, the least-squares regression fit between the actual energies and magnitude is

$$\log E_s = 4.4 + 1.5 M_s \quad (9)$$

which is plotted as the solid line in Figure 3. The  $a$ -value of 4.4 indicates that on average the original Gutenberg-Richter formula overestimates the radiated energy by a factor of two. To define energy magnitude,  $M_e$ , we replace  $M_s$  with  $M_e$  in Eq. (9)

$$\log E_s = 4.4 + 1.5 M_e \quad (10)$$

or

$$M_e = (\log E_s - 4.4)/1.5. \quad (11)$$

**Figure 3** Radiated energy ( $E_s$ ) of global data as a function of surface-wave magnitude ( $M_s$ ). The energy predicted by the Gutenberg-Richter formula,  $\log E_s = 4.8 + 1.5 M_s$  (in units of Newton-meters), is shown by the dashed line. From a least-squares regression, the best-fitting line with the slope of 1.5 is  $\log E_s = 4.4 + 1.5 M_s$  (according to Choy and Boatwright, 1995).

The usage of Eq. (11) is conceptually antithetical to that of Eq. (8). In Eq. (11) magnitude is derived explicitly from energy, whereas in Eq. (8) energy is dependent on the value of magnitude.

#### 4 The relationship of radiated energy to moment and apparent stress

The energy and moment for a particular earthquake are related by apparent stress,  $\sigma_{app}$  (see Equation (59) in IS 3.1),

$$\sigma_{app} = \mu E_s / M_0 \quad (12)$$

where  $\mu$  is the average rigidity at the source. When radiated energy,  $E_s$ , is plotted against seismic moment,  $M_0$ , for global shallow earthquakes (Figure 4), the best fit by least-squares regression of  $E_s$  on  $M_0$  (solid line) yields

$$E_s = 1.6 \cdot 10^{-5} M_0. \quad (13)$$

**Figure 4** Radiated energy,  $E_s$ , of 394 shallow-focus earthquakes as a function of seismic moment,  $M_0$ . The slope of the least-squares log-normal regression (solid line) yields a global average apparent stress  $\bar{\sigma}_{app}$  of about 0.5 MPa assuming a source rigidity of  $0.3 \cdot 10^5$  MPa. The 95% spread (or width of distribution) about the regression line is indicated by the dashed lines (according to Choy and Boatwright, 1995).

Assuming an average rigidity for shallow earthquakes of  $0.3 \cdot 10^5$  MPa, the slope of the regression line yields a worldwide average apparent stress,  $\bar{\sigma}_{app}$  of about 0.47 MPa. The spread about the regression line is very large. In terms of apparent stress it is between 0.03 to 6.69 MPa. Empirical formulas, like those employing  $M_0$  or  $M_s$ , ignore the spread and, thus,

would be poor predictors of energy. Viewing the spread of  $E_s$ - $M_0$  values about the regression line in terms of apparent stress, rather than random scatter, may provide significant insight into the physics of earthquake occurrence. For example, the release of energy and apparent stress could vary systematically as a function of faulting type, lithospheric strength and tectonic region (Choy and Boatwright, 1995). As more statistics on the release of energy are accumulated, spatial and temporal variations in energy release and apparent stress might also be identified.

## 5 The relationship of $M_e$ to $M_w$

Although  $M_e$  and  $M_w$  are magnitudes that describe the size of an earthquake, they are not equivalent.  $M_e$ , being derived from velocity power spectra, is a measure of the radiated energy in form of seismic waves and thus of the seismic potential for damage to anthropogenic structures.  $M_w$ , being derived from the low-frequency asymptote of displacement spectra, is physically related to the final static displacement of an earthquake. Because they measure different physical properties of an earthquake, there is no *a priori* reason that they should be numerically equal for any given seismic event. The usual definition of  $M_w$  is:

$$M_w = 2/3 \log M_0 - 6.0 \quad (\text{with } M_0 \text{ in Nm}). \quad (14)$$

The condition under which  $M_e$  is equal to  $M_w$ , found by equating Eq. (11) and Eq. (14), is  $E_s/M_0 \sim 2.2 \cdot 10^{-5}$ . From Eq. (12) this ratio is equivalent to  $\sigma_{app} \sim 2.2 \cdot 10^{-5} \mu$ . For shallow earthquakes, where  $\mu \sim 0.3\text{--}0.6 \times 10^5$  MPa, this condition implies that  $M_e$  and  $M_w$  will be coincident only for earthquakes with apparent stresses in the range 0.66–1.32 MPa. As seen in Figure 4, this range is but a tiny fraction of the spread of apparent stresses found for earthquakes. Therefore, the energy magnitude,  $M_e$ , is an essential complement to moment magnitude,  $M_w$ , for describing the size of an earthquake. How different these two magnitudes may be is illustrated in Table 1. Two earthquakes occurred in Chile within months of each other and their epicenters were less than  $1^\circ$  apart. Although their  $M_w$ 's and  $M_s$ 's were similar, their  $m_b$ 's and  $M_e$ 's differed by 1 to 1.4 magnitude units! Table 1 describes the macroseismic effects from the two earthquakes. The event with larger  $M_e$  caused significantly greater damage!

(1) Felt (III) at Coquimbo, La Serena, Ovalle and Vicuna.  
 (2) Five people killed at Pueblo Nuevo, one person killed at Coquimbo, one person killed at La Chimba and another died of a heart attack at Punitaqui. More than 300 people injured, 5,000 houses destroyed, 5,700 houses severely damaged, another 10,000 houses slightly damaged, numerous power and telephone outages, landslides and rockslides in the epicentral region. Some damage (VII) at La Serena and (VI) at Ovalle. Felt (VI) at Alto del Carmen and Illapel; (V) at Copiapo, Huasco, San Antonio, Santiago and Vallenar; (IV) at Caldera, Chanaral, Rancagua and Tierra Amarilla; (III) at Talca; (II) at Concepcion and Taltal. Felt as far south as Valdivia. Felt (V) in Mendoza and San Juan Provinces, Argentina. Felt in Buenos Aires, Catamarca, Cordoba, Distrito Federal and La Rioja Provinces, Argentina. Also felt in parts of Bolivia and Peru.

## 6 Regional estimates of radiated seismic energy

Radiated energy from local and regional records can be computed in a fashion analogous to the teleseismic approach if suitable attenuation corrections, local site and receiver effects, and hypocentral information are available or can be derived. Boatwright and Fletcher (1984) demonstrated that integrated ground velocity from S waves could be used to estimate radiated energy in either the time or frequency domain by,

$$E_s = 4\pi C^2 r^2 \rho_r \beta_r \int_0^\infty \dot{u}_c(t)^2 dt \quad (15)$$

$$= 4\pi C^2 r^2 \rho_r \beta_r \int_0^\infty \dot{u}_c(\omega)^2 d\omega \quad (16)$$

where the ground velocity has been corrected for anelastic attenuation,  $C$  is a correction for radiation pattern coefficient and free-surface amplification,  $r$  is the source-receiver distance, and  $\rho_r$  and  $\beta_r$  are density and S-wave velocity at the receiver. The attenuation correction is usually of the type  $\exp(\omega r/\beta Q)$ , where  $Q$  is the whole-path attenuation. Similarly, Kanamori et al. (1993) use a time-domain method to estimate the S-wave energy radiated by large earthquakes in southern California,

$$E_\beta = 4\pi r^2 C_f^{-2} [r_0 q(r_0)/r q(r)]^2 \rho_0 \beta_0 \int_0^\infty \dot{u}^2(t) dt \quad (3.66)$$

where  $\rho_0$  and  $\beta_0$  are hypocentral density and S-wave velocity,  $C_f$  is the free-surface amplification factor,  $r$  is the source-receiver distance estimated from the epicentral distance  $\Delta$  and a reference depth  $h$  of 8 km (such that  $r^2 = \Delta^2 + h^2$ ). Attenuation is described by  $q(r) = cr^{-n} \exp(-kr)$ , which is the Richter (1935) attenuation curve as corrected by Jennings and Kanamori (1983). For southern California earthquakes,  $c=0.49710$ ,  $n=1.0322$ , and  $k=0.0035 \text{ km}^{-1}$ .

## 7 Conclusions

Energy gives a physically different measure of earthquake size than moment. Energy is derived from the velocity power spectra, while moment is derived from the low-frequency asymptote of the displacement spectra. Thus, energy is a better measure of the severity of shaking and thus of the seismic potential for damage, while moment, being related to the final static displacement, is more related to the long-term tectonic effects of the earthquake process. Systematic variations in the release of energy and apparent stress as a function of faulting type and tectonic setting can now be identified that were previously undetectable because of the lack of reliable energy estimates. An energy magnitude,  $M_e$ , derived from an explicit computation of energy, can complement  $M_w$  and  $M_s$  in evaluating seismic and tsunamigenic potential.

## 1 Abstract

The paper aims at reviewing the development and use of the energy class (K-class) system since the late 1950s in the former Soviet Union (FSU) for quantifying the size of local and regional earthquakes, at comparing its results with current full-fledged estimations of released seismic energy and energy magnitude via the integration of teleseismic broadband velocity P-waveforms and at assessing the potential of modernized and standardized K-class determinations as a valuable complement to current teleseismic procedures. K-class in its original preliminary version was proposed by Victor Bune. His version was radically improved by Tatiana Rautian to constitute a rapid and simple means of estimating the radiated seismic energy  $E_s$  from an earthquake. K-class was defined as  $K = \log_{10} E_s$  with  $E_s$  in units of Joules. In practice, a graphical method was used based on the maximum horizontal (for S-wave) and vertical (for P-wave) amplitudes which was calibrated to independently determined energy estimates in Soviet Central Asia, and was used directly or with modifications as a standard throughout the FSU. The empirical relationships between K and classical magnitude scales vary somewhat between areas, but are, on the whole, consistent with magnitude-energy relationships proposed in the past fifty years, as well as with energy magnitude  $M_e$ . We show that the concept of the K-class can continue to be applied, with modifications, through the use of modern recording, filtering and data analysis tools and applied to regions outside the FSU as well as to the extensive historical data set from the FSU.

## 2 The development of the *K*-class system and methodology

After the devastating magnitude 7.4 Khait earthquake of 1949, the Complex (Interdisciplinary) Seismological Expedition was deployed by the former Geophysical Institute of the Soviet Union (USSR) in the Garm region of Tadjikistan to study its aftershocks and related phenomena. No specifications for seismic stations, procedures for measurements, standards for data processing, or necessary documentation had been established at that time. Thus, members of the expedition developed their own procedures. Due to the large number of events and limited computational and data analysis tools available, relatively simple, primarily graphical, methods were required.

In its original preliminary version, "Energy class K" was proposed by Bune (1955) with the intention to create a tool for absolute source energy calibration. It was based on integration of squared trace and theoretically would be a big advance with respect to the determination of magnitude *M*. Yet, in practice, it was unworkable with its hand-made integration on band-limited photographic records; it also used an imperfect way to reduce recorded wave energy to *E<sub>s</sub>*. To make the *K* scale workable in mass processing, Rautian (1958, 1960) made a critical step by returning to the measurement of peak-amplitude instead of integrating squared velocity amplitudes, thus developing a method to estimate earthquake energy that could be implemented by technical staff with only limited training, as summarized below. To calibrate her scale, Rautian performed hand integration of trace and *A/T* measurements in parallel for a large training data set. She also radically improved the source energy estimation procedure. A more detailed description of its development and calibration is presented in Rautian et al. (2007).

If seismic energy (*E<sub>s</sub>*) radiates uniformly, then at very short distances in a homogeneous Earth,  $E_s = 4\pi r^2 k\varepsilon$ ; where  $\varepsilon$  is the total energy density that crosses normal to a surface of a circular wave front with radius, *r*, per unit area, and *k* is a coefficient which accounts for a diversity of effects such as the Earth's surface topography and the ratio of the measured component to the full displacement vector. Since the short-period seismographs deployed in early years in and around Garm recorded displacement both amplitude and frequency would need to be measured to estimate  $\varepsilon$ ; however, visual "spectral analysis" of a seismogram by technicians was impractical and resulted in considerable scatter.

Both the terminology and the analysis of waves used in developing the *K*-class system have some ambiguity as they were selected more for operational purposes. *A* stands for the displacement amplitude of a specific oscillation, in recent usage generally the first arrival, and *A<sub>max</sub>* for the largest amplitude in the whole wave group belonging to a specific type of seismic phase. *T* refers to the period measured for a specific pulse with amplitude *A* or *A<sub>max</sub>*, whichever is being referred to, within the duration,  $\tau$ , of an arrival as measured from approximately the start to the end of oscillations with  $A > A_{max}/2$ . In practice, *A<sub>max</sub>* was, and is still, used in calculating and calibrating *K*.

Generally,  $\varepsilon$  depends on the amplitudes, frequency content, and signal duration of the analyzed seismic phases; however, observations at Garm showed that signal duration was controlled primarily by epicentral distance (due to the multiple scattering of waves in the structurally complex Earth medium in this mountainous area), whereas the frequency content in a wave group was largely controlled by the energy released by the earthquake and by its hypocentral distance (Rautian, 1960), due to the energy and stress-drop dependent shift of the corner frequency of the radiated source spectrum on the one hand, and frequency-dependent

attenuation on the other hand (see Sections 3). Thus, by measuring amplitude, which was easy to measure, alone, it was found that energy could be estimated to within a factor of 2 to 3, with proper regional calibration (i.e., by accounting in a rough manner for the combined impact of diverse parameters that influence the measured values). Moreover, to reduce the scatter and smooth the effect of the source radiation pattern, the sum of the **maximum** amplitude of the P wave on the vertical component ( $A_P$ ) and of the greater S-wave on one of the horizontal components ( $A_S$ ) was chosen, with P being Pg and S being Sg at local and shorter regional distances (usually < 400 km), whereas at larger regional distances, the measured arrivals could be Pg and Lg. This yielded a pragmatic solution. Operationally, especially in the continental regions of eastern Russia, Pg is the commonly measured P phase with very few Pn amplitudes ever picked. At distances of greater than 700-800 km (or less in central Asia and Baikal), Sg (Lg) is often the only amplitude measured.

To calibrate the amplitude measurements to energy, Rautian (1960) estimated the energy of a large number of earthquakes, predominantly from the northern Garm region, by visually measuring frequencies and amplitudes on particularly clear records, and using many other simplifying assumptions. In brief, the energy density,  $\varepsilon$ , was determined by summing all visually separable  $(Af)^2$ , which is proportional to the ground motion velocity squared, over the measured pulse duration  $\tau$ , where  $f$  is the measured frequency of a given cycle with displacement amplitude  $A$ . A correction,  $k$ , to account for frequency-dependent magnification of the seismograph, the use of only one record component instead of the complete vector, surface effects, etc., was estimated and applied. The dependence of  $k\varepsilon$  on distance,  $r$ , was observationally determined and then used to normalize the estimate of  $\varepsilon$  to  $r = 10$  km. Then,  $\log E_S(10 \text{ km}) = \log 4\pi k\varepsilon$ . Further, the amplitude measurements,  $[A_P(r) + A_S(r)]$ , were also normalized to  $r = 10$  km using an amplitude-distance relationship.

The measurements were made on short-period instruments, initially of type VEGIK, with a seismometer eigenperiod  $T_s = 0.8$  s, in common use in the 1950s and 1960s, later amended or replaced by Kirnos seismographs of type SKM and SK-III with slightly longer eigenperiod ( $T_s = 1.5$  s and 2 s, respectively), followed by the more medium to long-period Kirnos seismographs of type SK ( $T_s = 10$  s) and SKD ( $T_s = 20$ s). The approximate average displacement response curves of all these seismographs, compared with the response of the short-period Benioff seismographs in common use in the United States in these years, all normalized to a maximum magnification of 1, are depicted in Figure 1.

Amplitude measurements were typically made at periods < 3 s, i.e. for crustal S waves with a wavelength typically less than 10 km. As stated above, the K scale was calibrated to the energy flow through a focal sphere of radius  $r = 10$  km only. Such a sphere will, on the average, only enclose earthquake ruptures up to a magnitude of about 6. Therefore, the K-classification is principally suitable only for scaling local and regional earthquakes up to magnitudes of about 6 to 6.5 or  $K \leq 14$  to 15 (see sections 4 and 5 on magnitude-K relationships). For larger earthquakes which extend far beyond the size of the reference sphere and which release their maximum of seismic energy at periods  $\gg 3$  s the amount of released seismic energy will necessarily be underestimated (see Chapter 3, average seismic source spectrum and “saturation effect”).

**Figure 1** Normalized average displacement response curves of typical classical Soviet seismographs in comparison with the short-period US Benioff seismograph: **1** – Benioff; **2** – VEGIK with  $T_s = 0.8$  s; **3** – SKM with  $T_s = 1.5$  s; **4** – SK-III with  $T_s = 2$  s; **5** – SK with  $T = 10$  s and **6** – SKD with  $T_s = 20$  s.

For amplitude measurements on VEGIK records, the following empirical calibration formula was derived:

$$\log E_s \text{ (at 10 km in Joules)} = 1.8 \log [A_P(10 \text{ km}) + A_S(10 \text{ km})] + 6.4. \quad (1)$$

In terms of trivial physics, formula (1) looks a bit strange, because in the case of wave propagation in a homogeneous medium one would expect  $\log E_s \approx 2 \log A_{rms} + \log(\text{duration}) + \text{const.}$  But, according to formula (1), the waveform duration would then be  $\propto A^{-0.2}$ , i.e., it would decrease with amplitude, contrary to average observation. Yet, empirically, in real Earth, deviation from an ideal coefficient 2 may be correct and have also been found in other empirical magnitude-energy relationships, e.g., the relationship published by Gutenberg and Richter (1956) between  $\log E_s$  and body-wave magnitude  $m$  (with coefficient 2.2), and the one given by Richter (1958) between  $\log E_s$  and surface-wave magnitude  $M_s$  (with 1.5).

Moreover, also jumping back from considering in the original design of the scale  $\varepsilon$ , i.e., the total energy density crossing the circular wave front with radius  $r$  per unit area, to using the peak amplitude recorded at seismic stations instead, is significant and conceptually problematic. But in practical terms this step was unavoidable with hand measurements and, therefore, does not deserve any criticism.

Formula (1) yields an amplitude sum,  $A_P(10 \text{ km}) + A_S(10 \text{ km})$ , of 100 microns for  $\log E_s$  of 10. The shape of this calibration curve with distance was similar to that of Richter's (1935) local magnitude  $M_L$  but included deviations that were later explained as possibly being due to

refractions from the Moho or other arrivals, as well as to changing spectral content of waves with distance.

For simplicity in practical use, the log-distance scale was adjusted to make the amplitude-distance curves straight lines, as in Figure 2. Thus while the distance axis appears to be logarithmic, close examination of it shows that the horizontal scale was adjusted to incorporate the deviations.

**Figure 2** The Rautian (1964) K-class nomogram calibrated for SKM, VEGIK, and SK seismometers. Note that the horizontal distance scales are not truly logarithmic; see text for explanation. Vertical axis: sum of P and S-wave amplitudes in microns (modified from Figure 2 in Rautian et al., 2007, *Seism. Res. Lett.*, **78**(6), p. 582, © Seismological Society of America).

Since the calibration to  $E_s$  depends on the response of the seismograph, the calibration curves should have been adjusted as new instruments with different responses were deployed. However, the derivation of new calibration formulas for K for newly introduced instrumentation would have required a tremendous amount of empirical and theoretical work.

Moreover, the most commonly measured frequencies of local earthquakes (2-5 Hz) were such that the differences in instrument response did not appear to significantly change the results. Therefore, the same nomogram was used and only the distance scales were adjusted for different instruments (Rautian, 1964). Figure 2 shows the respective nomograms for calibrating the sum of P and S amplitude readings on short-period Kirnos SKM and VEGIK as well as on medium-period SK records, which continue to be used until now. The mismatch between the K-scales for different instruments reflects the fact that their passbands probe different parts of the source spectrum.

SKM seismographs became the main instrument for K-determination. They had typically a seismometer eigenperiod,  $T_s$ , around 1 to 2 s, a galvanometer period,  $T_g$ , around 0.3 s, and a damping of the seismometer and galvanometer chosen so as to produce a displacement-proportional response in the frequency range between some 0.5 and 20 Hz (see Figure 1).

Today, digital broadband seismograms could easily be accommodated by filtering such records to simulate the records with instrument responses of either the VEGIK, SKM or SK instruments. On Kamchatka, this is now routine procedure, i.e., converting BB digital velocity traces to 1.2s-instrument galvanometric traces of pre-digital era, and calculation of K values from S-waves. We are unaware, however, whether digital recordings in the FSU are nowadays routinely filtered everywhere before measuring parameters such as K – to emulate one of the historic instruments so as to remain compatible with the original definitions and baselines.

Because of the many simplifying assumptions made and uncertainties involved, the scale was called “energy class” instead of “energy” (see also below). Using the Russian spelling класс, the scale was defined as  $K = \log E_s$ , with  $E_s$  in Joules. The first outline of this scale was presented in Rautian (1958) and updated in Rautian (1960). The scale had its problems, but was easy to apply with the facilities and personnel of the time. K-class was adopted to quantify the size of earthquakes throughout the former USSR by 1961 and continues to be used today. Outside the USSR, K-class was used extensively only in Mongolia and in Cuba..

The standard deviation in K-class estimates between stations, due to site effects, station distribution with respect to the radiation pattern, heterogeneities in the crust, using only one horizontal component, etc., was empirically determined to be about 0.35 log units. No site corrections were originally used; however, they were later added by some networks.

In current practice, networks use only the maximum horizontal displacement amplitudes for K determination, usually at hypocentral distances up to about 600 km (see Figures. 2 and 4 to 6), since the amplitude of  $S_g$  (or  $L_g$ ) dominates that of  $P_g$ .  $S_g$  and  $L_g$  are not differentiated and simply referred to as  $S_g$ , even at distances up to 1500 km where  $L_g$  is often still observed on the craton. These arrivals typically have dominant periods below 2.5 s. Operationally, the typical range of periods measured for determining K-class values today is 0.2 to 1.1 s. (see Figure 3). P-arrivals are seldom used in continental eastern Russia; S is used in place of  $S_g$  in the Kuriles and S and P are independently used on Kamchatka.

**Figure 3** Average histogram of periods at which P and/or S-wave amplitudes have been measured by different local networks in the FSU for estimating the K values of mostly local earthquakes between 1978 and 2009.

In summary, K estimates, being based on short-period P- and S-wave amplitudes with periods less than 2 s, and wavelengths typically less than 10 km, are suitable only for scaling local and regional earthquakes with magnitudes up to 5.5 or 6 at most, corresponding to  $K \approx 14$  to 15. For larger earthquakes, the amount of released seismic energy will necessarily be underestimated (“saturation”).

### 3 Regional variations of the K-class method

K-class (or more correct, K-magnitude) was adjusted regionally in the FSU to significant degrees. This is indispensable, as for other short-period local/regional magnitude scales applicable in different seismo-tectonic environments (e.g., ML and mb\_Lg; see IS 3.3 and Table 2 in DS 3.1).

As noted, the routine K-class calculations ignored the specific spectral content of the individual displacement records, which was observed to differ randomly between events in the same area, and systematically between events in different tectonics settings. Thus, when calculated from displacement only, K is more closely related to the logarithm of the seismic moment,  $M_0$ , than to  $\log E_S$  as calculated by using velocity spectra.

The ratio between these two parameters may vary regionally, depending on the seismotectonic environments such as continental crust, subduction zones, deep seismic zones, oceanic ridges, etc. and thus also on the predominant type of source mechanism (e.g., Choy and Boatwright, 1995; Choy et al., 2006; Kanamori and Brodski, 2004; Bormann and Di

Giacomo, 2011). On a global scale the variability reaches about 3 orders of magnitude. It is mainly related to the differences in stress drop, or “apparent stress” (Wyss and Brune, 1968), but also to variable rigidity in the yielding earthquake source volume (e.g., Houston, 1999; Polet and Kanamori, 2000) and thus to “fault maturity” (see IS 3.5). In this context one should note that both stress drop and rigidity are considered to be constant in  $M_0$  calculations.

Another useful related parameter is “earthquake hardness  $S_M$ ”. This term was originally introduced by N.V. Shebalin to describe the deviation of macroseismic intensity (see Chapter 12) from its average value at a given  $M_s$ , which are closely related to differences in the high-frequency content of the seismic wave field in the shaken areas. Thus,  $S_M$  is quite relevant for describing variations of the  $E_s/M_0$  ratio too. The correspondence between  $K$  and  $M_0$  was found on FSU territory to be best in crystalline rocks and regions of thrust tectonics ( $S_M \approx 0$ ) and worst (significantly negative  $S_M$ ) for strike-slip events within strongly fractured rocks with low-frequency source spectra.  $S_M$  was found to be significantly positive for intermediate-depth events.

With respect to the Kurile Islands, Fedotov used in 1963 S-wave amplitudes only and replaced the proper distance scale (as used, e.g., in Rautian, 1964) by S-P time (as in Figure 4). His scale was usable for earthquakes in a wide depth range of the Kurile Islands environment. The K-Fedotov63 was improved in 1968, and additionally an analog P-wave K-scale was proposed. Both Fedotov K-scales are still in use on Kamchatka, but their calibration curves and also the way of their absolute calibration are radically different from the Rautian K scale (for details see Fedotov, 1972). This applies, more or less, to other regional K-class formulas as well. Note that on Kamchatka it is routine practice to use besides the two Fedotov K scales also a coda-class Kc. The latter is very efficient when S-wave amplitudes are off scale on photographic records, or out of the dynamic range on a digital channel (see Lemzikov and Gusev, 1991).

**Figure 4** The 1967 Kurile nomogram for calibrating  $A/T$  with  $A$  measured in micron ( $\mu$ ) and  $T$  in seconds on SK records. The horizontal axis is linear in differential S-P travel time, which is proportional to hypocentral distance, in this diagram up to about 250 km (copied from Figure 5 in Rautian et al., 2007, *Seism. Res. Lett.*, **78**(6), p. 585, © Seismological Society of America).

The Kamchatka and Sakhalin regional networks are both located in subduction zone settings with very different velocity structure,  $L_g$  propagation, and a stronger attenuation, than in the continental regions. Thus, they developed their own  $K$  scales (see Rautian et al., 2007) based on using only  $A_{Smax}$ , but normalized by the period,  $T$ , and thus being a measure of the maximum S-wave ground motion velocity. The calibration techniques were similar and different calibration relationships were developed for shallow and for intermediate depth earthquakes. The Sakhalin network nomogram, used in the Kurile Islands for scaling SK records (see Figure 4), and Kamchatka nomograms for scaling SKM records (see Figure 5) were revised several times as both networks were expanded and more data was acquired. In the compilation by Kondorskaya and Shebalin (1977), the 1961 scale (Fedotov et al., 1964;  $K_F$ ) and 1967 scale (Solov'ev and Solov'eva, 1967;  $K_S$ ) were converted to Rautian (1960)  $K$ -class values using  $K = K_F + 0.6$  and  $K = K_S + 1.7$ .

**Figure 5** The current Kamchatka nomogram for scaling  $A/T$  measured on SKM records. Dashed lines represent limits of integer determinations. Vertical axis amplitude is in microns ( $\mu$ ), period,  $T$ , in seconds. The horizontal axis is logarithmic in S-P travel time, and corresponds to hypocentral distances up to about 640 km (copied from Figure 6 in Rautian et al., 2007, Seism. Res. Lett., **78**(6), p. 585, © Seismological Society of America).

A  $K$ -class nomogram was also developed for the Crimea (Pustovitenko and Kul'chitsky, 1974), although it is unclear how extensively it was used. Recently, Adilov et al. (2010) published  $K$ -class nomograms for Dagestan utilizing  $A_P$  only,  $A_S$  only, and  $A_P + A_S$  (Figure 6), using data from 1994-1997. As elsewhere,  $A_S$  dominates and therefore a reasonable approximation can be obtained from  $A_S$  data alone, especially at lower  $K$  values. According to Kondorskaya et al. (1981) the definition of  $K$  on the nomograms gives satisfactory results to within  $\pm 0.5 K$ , which corresponds to about 0.3 m.u. (magnitude units).

The Baikal (Solonenko, 1977) and Caucasus (Dzhibladze, 1971) networks also calculated regional attenuation curves and K nomograms for their regions; however, in both cases, the results were fairly close to those of the Rautian (1958) formulation and therefore these regional nomograms were not put into use. K has also been back-estimated from various magnitudes and, specifically in the northern Caucasus, from duration magnitudes for estimating a duration K (Gabsatarova, 2002).

**Figure 6** The Dagestan nomogram for SKM seismometer records. Vertical axis is in  $\log A$  in microns ( $\mu$ ) and the horizontal axis is logarithmic in distance ( $r$ ) in km, here up to 300 km. (copied from Figure 4 in Adilov et al., 2010),

In summary, we realize a need to derive regional calibration relationships for short-period K estimates, aimed at classifying mainly local and regional earthquakes down to very small size. If properly done, they would allow us to compensate for the unavoidable and often very significant variations in local/regional wave propagation conditions, thus making data derived by different networks, for events in different regions, compatible. This is the same situation as for the classical local magnitude scale  $M_L$ , which is applied in the same frequency range as the K scale. Meanwhile numerous regional  $M_L$  calibration relations have been published (see DS 3.1). Yet, one of the disadvantages of the K class is currently the inconsistency in which some of these regional formulas have been derived and scaled (e.g., using only P or S or the sum of P+S amplitudes, only A or A/T, and different types of responses for deriving or applying such relationships). Thus there is an urgent need for standardization of procedures compatible with modern recording and processing techniques. In conjunction with related international efforts for standardization of the procedures for the calculation of the most common magnitude measurements are needed that ensure the global compatibility of values of the same type, and the stability of the relationships between complementary types of parameters describing earthquake size or strength (see, IS 3.3 specifically, and Chapter 3 in general).

## 4 Relationship of K class to magnitude scales

(Note: In the following we use two types of magnitude nomenclature:

a) the NMSOP generic nomenclature which generally writes magnitude symbols not in *Italics* and without subscript and prefers to write the local magnitude in general as *Ml* instead of the original Richter (1935)  $M_L$  or the new IASPEI (2011) standard *ML*; b) the nomenclature for the IASPEI (2005 and 2011) approved standard magnitudes *mb*, *ML*, *Ms\_20* and *Ms\_BB*.

Magnitude, *M*, began to be used throughout the USSR for larger earthquakes starting in 1955. The so-called “Prague-Moscow magnitude” formula for surface-waves (Vanek et al., 1962) became the accepted standard in the annual *Earthquakes in the USSR (Zemletryaseniya v SSSR)* starting with the 1962 compilation and became the international IASPEI standard in 1967. This magnitude, *Ms\_BB* when written in recent IASPEI standard nomenclature (see below), was computed using the ratio  $(A/T)_{max}$  of the whole surface-wave train in a wide range of periods between 3 s and 30 s (more recently extended to 60 s), originally as recorded by medium-period (SK) and the more long-period (SKD) Kirnos type broadband displacement seismographs (see Fig. 1) in the distance range between 2° and 160° (today measured directly from very broadband velocity meters; see Bormann et al., 2009 and IS 3.3).

Since local and regional networks in the FSU primarily used short-period instruments, the calculation of K class for stronger events with longer period energy was not possible. Thus K class was generally calculated for smaller events, while magnitude was calculated for larger events; however, both were potentially calculated for magnitudes between 4 and 5.5 (corresponding to K class 11 to 14).

The primary difference between K class and *M* is that K class is technically calibrated to energy. Empirically, the 20 s *Ms*, now standard *Ms\_20*, has also been scaled to seismic energy by Richter (1958) using the log *Es*-*mB* and *mB*-*Ms* relationships in Gutenberg and Richter (1956) and, more recently, by Choy and Boatwright (1995) based on direct *Es* estimates from velocity broadband records (see discussion below). The “Prague-Moscow” *Ms*, equivalent to current standard *Ms\_BB* (see IS 3.3), is presumed to be even more directly related to seismic energy than *Ms\_20* since it measures  $(A/T)_{max}$  over a much wider period range. As originally developed, by using amplitudes of both P and S waves, K-class utilized a somewhat better estimate of the overall ground motion, thus making it less dependent on the effects of the focal mechanism. On the other hand, longer period surface wave measurements will be less affected by attenuation and scattering in heterogeneous media and by local site effects.

As noted above, since  $A_S$  dominates over  $A_P$ , many K values calculated throughout Russia today are only based on  $A_{Smax}$ , e.g., in Kamchatka and Sakhalin, so that they should be viewed as being in fact an equivalent to *Ml* and are considered as such in the ISC Bulletin.

Since *Es* is proportional to  $A^2$ , assuming constant *T*, the relationship between K and *Ml* should be of the form

$$Ml = c + 0.5 K \quad (2)$$

where *c* is a constant. However, variations in attenuation and radiated energy spectra, source depth, and tectonic styles will cause differences both between, and within, regions. Conceptionally, formula (2) is disputable because signal duration is not taken into account, yet still it may work in practice reasonably well.

According to Rautian (1960), early studies for Tadzhikistan yielded

$$M = (M_L) = -2.22 + 0.56 K = -2.22 + 0.56 (\log E_S) = 5.62 + 0.56(K - 14) \quad (3)$$

in the K class range  $4 \leq K \leq 13$ .

In this context it is worth mentioning that Berckhemer and Lindenfeld (1986) found that when calculating energy from broadband velocity records,  $\log E_S \sim 2 M_L$ , which corresponds precisely to (2), and is close to (3), the original empirical estimate by Gutenberg and Richter (1956) for Southern California ( $\log E_S \sim 1.92 M_L$ ), and to the much more recent relationship derived by Kanamori et al. (1993) based on US TERRAScope data:

$$\log E_S = 1.96 M_L + 2.05 \quad (4a)$$

which could also be written as

$$M_L = 6.1 + 0.51 (K - 14). \quad (4b)$$

Since K class is calculated from short-period instruments, like mb and  $M_L$ , it saturates at around  $K \approx 15$  to 17 or  $M \approx 6$  to 7, unlike  $M_S$ , which saturates around 8-8.5 (Kanamori, 1983), corresponding to  $K \approx 18$ -19.

To determine the variations between regions of the empirical relationship between M and K class, Rautian et al. (2007) tabulated M and K class values reported for 1970-1997 for each of the seismic regions used in *Earthquakes in the USSR*, and its successor publications, and compared them with mb and  $M_S$  values reported in the catalog of the International Seismological Centre (ISC). Because K class and M are both independent variables with their own uncertainties, they used an orthogonal regression which minimized the sum of the squares of the distance to the regression line in both the ordinate and abscissa directions. Because K class tends to be calculated for smaller events, and magnitude for larger events, and both are calculated using different methods (see above, for K, and Chapter 3 and IS 3.3 for  $M_S$ ) there is some inconsistency and scatter in the different magnitude – K class ( $\log E_S$ ) relationships (for more details see Rautian et al., 2007; also Sadovsky et al., 1986, and Riznichenko, 1992). All regressions in Rautian et al. (2007) and in Table 1 were standardized to the general form

$$M = c + s (K - 14). \quad (5)$$

By using  $K - 14$ , the sign on c is always positive and makes comparisons clearer in the range  $9 \leq K \leq 14$  where both K and M are likely to have been calculated.

The mb regressions (see Figure 7a and for details Table 1) are generally similar, close to an average relationship of

$$mb = 5.41 + 0.43 (K - 14) \quad (6)$$

in the K class range of interest ( $9 \leq K \leq 14$ ), except for the Crimea, Sakhalin, Kurile, and Kamchatka. The Crimea, Sakhalin, and Kamchatka regions have higher constants and slope values than the other regions, while Kurile region has a similar slope, but a larger constant. The different constants suggest differences in attenuation conditions, and different slopes point to different amplitude-distance-source-depth conditions and relationships than those on which the magnitude and K class formulas are based. This clearly applies to the three Far Eastern regions (Sakhalin, Kurile, Kamchatka), which have different tectonic settings in

subduction zones with a different and more complex velocity structure and attenuation conditions. This explains why their K formulas differ significantly from the rest of the former USSR. It is interesting that the Kurile regression differs from both Sakhalin (which administers the Kurile network) and Kamchatka (which is tectonically similar).

For Central Asia, where Rautian (1958) developed the K class scale, Rautian (1960) gave the relationship  $m_b = 5.48 + 0.55 (K - 14)$  and Rautian et al. (2007) calculated  $m_b = 5.53 + 0.449 (K - 14)$ ; both are close to the average relationship given in (6).

If one replaces K by  $\log E_s$  in equation (6) and solves for  $\log E_s$  in order to make it comparable with classical  $\log E_s$ -M relationships, one obtains

$$\log E_s = 2.326 m_b - 1.42 \quad (7)$$

which has a slope remarkably similar to the original Gutenberg and Richter (1956) relationship

$$\log E_s = 2.4 m_B - 1.2 \quad (8)$$

although Eq. (8) is meant to be used for the medium-period broadband  $m_B$  measured by Gutenberg at periods between 2 s and 20 s (primarily between 5 s and 10 s) and not for the short-period  $m_b$ . However, for equal values of  $m_b$  and  $m_B$  between 5 and 7, Eq. (8) yields energy values 4 to 5.5 times larger than from Eq. (7). Moreover, for equal events, broadband  $m_B$  is generally larger than  $m_b$  (on average by about 0.3 – 0.5 m.u. between  $m_b = 5$  and 7 and this difference increases further with magnitude. Thus, event estimates of  $E_s$  in this magnitude range are about 8 to 17 times larger when based on  $m_B$  than those based on  $m_b$ .

**Table 1** Regressions between K class and magnitudes\*

| Region        | $m_b$                   | $M_s$                   | $M_e$                 | N( $M_e$ ) | $M_e$<br>$r^{2**}$ |
|---------------|-------------------------|-------------------------|-----------------------|------------|--------------------|
| Carpathians   | $5.54 + 0.397 (K-14)$   | $5.92 + 0.661 (K-14)$   |                       |            |                    |
| Crimea        | $6.20 + 0.699 (K-14)$   | Insufficient Data       |                       |            |                    |
| Caucasus      | $5.60 + 0.391 (K-14)$   | $6.02 + 0.782 (K-14)$   | $6.49 + 0.547 (K-14)$ | 8          | 0.61               |
| N-Caucasus    |                         |                         | $5.23 + 0.635 (K-14)$ | 3          | 1.00               |
| Kopetdag      | $5.53 + 0.467 (K-14)$   | $5.71 + 0.781 (K-14)$   | $5.15 + 0.672 (K-14)$ | 5          | 0.93               |
| Central Asia  | $5.53 + 0.449 (K-14)$   | $5.36 + 0.594 (K-14)$   | $5.73 + 0.218 (K-14)$ | 15         | 0.10               |
| Altai - Sayan | $5.47 + 0.482 (K-14)$   | $5.37 + 0.633 (K-14)$   | $5.79 + 0.517 (K-14)$ | 5          | 0.59               |
| Baikal        | $5.23 + 0.434 (K-14)$   | $5.54 + 0.828 (K-14)$   | $5.13 + 0.474 (K-14)$ | 5          | 0.60               |
| Yakutia       | $5.49 + 0.427 (K-14)$   | $5.55 + 0.539 (K-14)$   | Insufficient data     |            |                    |
| Northeast     | $5.33 + 0.445 (K-14)$   | Insufficient Data       | Insufficient data     |            |                    |
| Amur          | $5.01 + 0.394 (K-14)$   | $5.10 + 0.755 (K-14)$   |                       |            |                    |
| Sakhalin      | $7.25 + 0.669 (K_S-14)$ | $7.57 + 0.773 (K_S-14)$ | Insufficient data     |            |                    |
| Kurile***     | $6.30 + 0.460 (K_S-14)$ | $6.56 + 0.642 (K_S-14)$ | $6.93 + 0.729 (K-14)$ | 18(39)     | 0.85               |
| Kamchatka     | $6.11 + 0.552 (K_F-14)$ | $6.47 + 0.838 (K_F-14)$ | $6.26 + 0.657 (K-14)$ | 52         | 0.66               |

\*  $m_b$  and  $M_s$  correlations from Rautian et al. (2007).

\*\*  $r^2$  is Pearson's correlation coefficient squared.

\*\*\* see Rautian et al. (2007) for calculation methodology; for N( $M_e$ ) the number of bins is given, the number of total data points is in parentheses.

Ms regressions by Rautian et al. (2007) are more variable (Figure 7b, Table 1), reflecting the fact that the methodology and frequencies used for calculating mb and K are much closer than those for determining Ms. Further, one has to distinguish between Ms as generally reported by NEIC, measured in a the narrow range of periods between 18 and 22 s at teleseismic distances between 20° and 160° only, and the broadband Ms measured today at periods between 3 s and 60 s and in a wider distance range between 2° and 160°. Although both these values of Ms are calculated according to the “Prague-Moscow” IASPEI standard formula  $M_s = \log(A/T) + 1.66 (\log \Delta^\circ) + 3.3$ , the former, now termed Ms\_20, is mostly used in western countries and at all stations and centers reporting to the NEIC, whereas the latter, now termed Ms\_BB, is the more correct application of the “Prague-Moscow” formula and has been used ever since its development in the FSU and allied countries, as well as by China. The orthogonal Ms-K relationships tabulated by Rautian et al. (2007) use Ms values published by the ISC, which are based on a mix of both types of data, depending on what has been reported to it.

The slopes of Rautian et al. (2007) regressions vary from 0.5 to 0.8 with a mean regression of

$$M_s = 5.52 + 0.702 (K - 14), \quad (9)$$

excluding the Carpathians, which are based on very limited data, and the subduction zone networks of the Russian Far East, which have  $c$  values  $> 6.4$  and used different methodologies for calculating K as noted above. In general, however, most of the curves are fairly close to each other in the range  $10 \leq K \leq 14$  (Figure 7b).

In this context we also draw the attention to the non-linear relationships between K-Fedotov and Mw (see Figure 9) as well as the linear relationships between K-Fedotov and the short-period Obninsk mPVA = mSKM, published by Gusev and Melnikova (1991) and Gusev (1992). Note that mb(NEIC, ISC) is on average smaller by about 0.18 magnitude units than mPVA = mSKM, because mb is mostly measured on records with responses similar to that of the Benioff instrument with a slightly lower seismometer eigenperiod and a narrower bandwidth than SKM.

Russian regional events listed in western seismicity catalogs, including the ISC, are reported with magnitudes calculated from K class using locally derived regressions, although this is not always clearly stated, resulting in uncertainty as to which the primary determination was. Moreover, there have been procedural changes which affect how the magnitudes were calculated from K class which bias reported values. For examples see Rautian et al. (2007).

**Figure 7** Comparisons of linear orthogonal regressions between K class and (a) mb and (b) Ms for various regions of the FSU. Most regressions fall within the shaded region; the mean of those regressions is shown as black line and corresponds to the formulas (6) for mb and (9) for Ms, respectively. Outlier regressions for Sakhalin, Kuriles and Kamchatka are shown and labeled separately (copied from Figure 8 in Rautian et al., 2007, *Seism. Res. Lett.*, **78**(6), p. 586, © Seismological Society of America).

Replacing K by  $\log E_s$  in (9) one obtains

$$\log E_s = 1.424 M_s + 6.14. \quad (10)$$

The slope is similar but with a very different constant relative to the commonly cited relationship  $\log E_s = 1.5 M_s + 4.8$ , derived (see below) from the relationships published by

Gutenberg and Richter (1956). The constant in (10) is even more different than that in the relationship  $\log E_S = 1.5 M_s + 4.4$ , derived by comparing NEIC  $M_{s\_20}$  with  $E_S$  measurements obtained by direct integration and Earth model scaling of squared P-wave velocity amplitudes (Choy and Boatwright, 1995). However, almost all data calculated by Choy and Boatwright (1995) are from  $M_s$  values between about 5.5 and 8.5, i.e., strong earthquakes, at which  $K$  values tend to saturate or are already saturated. This might explain the very large constant in (10) which results in an underestimation of  $M_s$  as derived from  $K$  for weak earthquakes ( $K < 10$ ). This likely could be corrected by correlating  $K$  not with the  $M_{s\_20}$  dominated ISC  $M_s$  but rather with  $M_{s\_BB}$ , which is applicable in the near regional range also for periods much smaller than 20 s. Bormann et al. (2009) showed that, on the average,  $M_{s\_20} = 3.5$  is equivalent to  $M_{s\_BB} = 4$ . Such a revised  $K$ - $M_{s\_BB}$  correlation is strongly recommended in the future when more  $M_{s\_BB}$  data, now a IASPEI standard (see IS 3.3), become available on a global scale, the FSU included. This will allow a direct correlation of data determined by these two independent approaches with different instruments. Regardless, in the range of  $K$  between about 12 and 16,  $M_s$  estimates determined using (9) are reasonable, with errors likely to be smaller than about 0.5 magnitude units.

Finally, we refer to the extremely important compilation of data by Riznichenko (1992), comparing  $K$  and  $M$  with  $\log M_0$  in relation to stress drop variations by more than three orders from 0.01 to more than 10 MPa (Figure 8).

**Figure 8** Correlation of source length  $L$  with magnitude  $M$  and energy class  $K$  according to data from various sources (e.g., curve 1 by Tocher, 1958, curve 2 by Iida, 1959; curve 6 average by Riznichenko, 1992; curves 3 to 5 from other authors quoted in Riznichenko, 1992). Thin straight lines: the associated stress drop,  $\Delta\sigma$ , are given in MPa; broken lines mark the limits of the 68% confidence interval with respect to the average curve 6 (modified from Riznichenko, 1992, Fig. 3; with permission of Springer-Verlag).

The values of  $M$  given in this diagram on the abscissa, along with  $K = \log E_s$ , correspond, depending on the distance and event size, to either  $M_L$  (for values  $< 4$  to about 6),  $mb$  (for  $> 4$  to about 5.5),  $mB$  (between about 5.5 to 7.5) or  $M_s$  ( $> 6$  to about 8.5). The  $M$  and  $K$  values given on the abscissa correspond to the following average “global” relationships between  $K$  and  $M$ :

$$\log E_s \approx K = 1.8 M + 4.1, \quad (11)$$

$$M = 0.556 K - 2.3 \quad \text{or} \quad (12)$$

$$M = 5.5 + 0.556 (K - 14) \quad (13)$$

with the understanding as to which approximate type of specific magnitude,  $M$ , this applies to in different magnitude ranges. The range of uncertainty is on the order of about 0.3 magnitude units. If one compares Eq. (13) with the Eq. (4b) for  $M_L$ , (6) for  $mb$  and (9) for  $M_s$ , then one realizes that the constants in all these relations are within a few tenths, that the slope in (13) is very close to that in (4b) for  $M_L$ , and in between, the slopes are 0.43 for the  $mb$ - $K$  and 0.70 for the  $M_s$ - $K$ . The agreement between Eqs. (4b) and (13) could likely be further improved by correlating  $K$  specifically with  $M_s$ \_BB, using values determined in the local and regional distance range, typically measured at periods between 2 s and  $< 15$  s.  $mb$ , however, is generally not as good an estimator for earthquake size and energy release for magnitudes above 5.5, for which  $mB$ \_BB is better suited. Yet, since  $mb$  is measured in the teleseismic range only, few values are available for event magnitudes below 3.5. Therefore, in the local and regional distance range,  $K$  and  $M_L$  are better estimators of the released seismic energy for smaller earthquakes, and  $M_s$ \_BB for stronger earthquakes.

When working with small earthquakes, it is often useful to relate  $K$  values to  $M_w$  which is practically a standard reference magnitude at present. Direct determination of  $M_w$  meets with an obstacle for small earthquakes: their flat low-frequency part of the displacement spectrum is rarely observed with an acceptable signal-to-noise ratio. Thus  $M_0$  or  $M_w$  are impossible to determine en masse on a routine basis, and catalogues of small earthquakes inevitably contain  $K$  (or  $M_L$ ) as a main magnitude value. To convert these catalogue values to  $M_w$  at least approximately, an adequate  $M$  to  $M_w$  relationship is a must. .

Figure 9 gives non-linear relationships between different  $K$  scales,  $M_L$ ,  $mB$ , and variants of  $mb$ , on one side, and  $M_w$ , on the other side. The  $mb$  values are based on records with short-period Benioff or WWSSN-SP instruments, respectively equivalent simulation filter responses (NEIC practice) and  $mb$ SKM is from SKM-3 instrument (Obninsk practice). The  $mb_n(M_w)$  trend reflects  $mb$  values obtained through older NEIC practice with narrow time window of amplitude measurement; see figure caption for details. Figure 9 is partly based on average relationships published by Gusev and Melnikova (1991) and Gusev (1992), extended here to the  $M_w = 2$ -5 range. Various other sources were also used; the most significant ones are Hanks and Boore (1984) and Tan and Helmberger (2007).

**Figure 9** Various K-classes and magnitudes vs. moment magnitude  $M_w$ . The left ordinate scale is K-class. Corresponding relationships (solid curves) are given for Fedotov (1968) S-wave K-class used on Kamchatka, Soloviev (1967) K-class used at Sakhalin for Kurile Islands, and Rautian (1960) K-class used in Central Asia and, in modified form, for many other continental areas of the FSU. The right ordinate scale is magnitude. Corresponding relationships (broken and dotted lines) are given: for classic local magnitude  $M_l$ ; for variants of mPV measured on short-period Benioff or WWSSN-SP type of records within a narrow measurement time window of 5-10s after the P-wave first arrival, denoted  $mbn$ ; its new IASPEI standard variant measured within an “unlimited” time window between the P and PP first arrival (see IS 3.3), denoted  $mb$ ; the similar Russian mPV variant measured on slightly longer-period SKM-3 records, denoted  $mbSKM$  (with  $mbSKM \approx mb + 0.18$  on average); and for medium-period, traditional  $mB$  of Gutenberg.

Note that the relationships  $M_l$  vs.  $M_w$  or  $K$  vs.  $M_w$  vary significantly between regions and even sub-regions. Therefore, the curves in Figure 9 can serve only as a preliminary reference. The “saturation effect” for body-wave magnitudes is clearly seen on Figure 9. Yet, it should be kept in mind that true saturation takes place only for  $mbn$  that scatters around the  $mbn = 6.4$  level at  $M_w \geq 7.5$ . In contrast,  $mb$  values based on amplitude readings within “unlimited” P-wave measurement time windows such as IASPEI standard  $mb$  (Bormann et al., 2009), its forerunner applied by Houston and Kanamori (1986), and the Obninsk  $mbSKM$  (Gusev and Melnikova, 1991) keep growing up to  $M_w$  around 9, attaining then values of about 7.4 to 7.6.

Note that recently, the Kamchatka network began to publish regional  $M_l$  directly calculated from the Fedotov (1968) S-wave K-class via the conversion relationship

$$M_l = 0.5K_F - 0.75. \quad (14)$$

This relationship is in agreement with the related curves of Figure 9. Interestingly, (14) is slope-wise identical with the equivalent formula (4b) derived above for California, although the constants differ by 0.29 m.u.. Accordingly, for equal  $K = \log E_S$ , Eq. (14) would yield about 0.3 m.u. smaller  $M_L$  values than (4b), hinting to regional differences in attenuation, the latter being larger in Kamchatka.

## 5 Future development and use of $K$ for energy-related earthquake classification

The paper by Rautian et al. (2007) reviewed the  $K$  classification of earthquakes mainly to

- explain the methodology of its development and modifications over time in different seismotectonic regions of the FSU,
- provide the most recent relationships between  $K$  and the  $m_b$  and  $M_s$  magnitudes as published by the International Seismological Centre, and
- give recommendations - sometimes cautionary - for the interpretation and use of the extensive  $K$ -class data available in current Russian and past FSU catalogs in terms of common magnitude scales, so as to make seismicity data for the vast territory covered by the  $K$  class system compatible with those of the rest of the world.

However, in this section, we would like to go one step further and look at the  $K$ -class system not only from a historical and data compatibility perspective, but in terms of the merits of this approach in general.

It is interesting to note that Gutenberg and Richter (1956) published the first semi-empirical energy-magnitude relationship, based on rather meager data, relating energy in Joules (J), to body-wave magnitude:

$$\log E_S = 2.4 m_B - 1.2 \quad (15)$$

Combining (15) with the Gutenberg and Richter (1956) body-wave to surface-wave magnitude conversion relationship,

$$m_B = 0.63 M_s + 2.5 \quad (16)$$

the often quoted Gutenberg-Richter magnitude energy relationship

$$\log E_S = 1.5 M_s + 4.8 \quad (17)$$

is obtained. Hanks and Kanamori (1979) based their scaling of seismic moment  $M_0$  to  $M_s$ , and thus the definition of their moment magnitude scale,  $M_w$ , on this relationship. Also the Russian authors of the  $K$ -class system calculated  $E_S$  in Joules from this equation, even though it is based on 20 s surface waves, which are not representative for the assessing the high-frequency related damage potential of earthquakes or the total seismic energy release of smaller earthquakes with corner frequencies well above 0.1 Hz. Gutenberg and Richter (1956) published only Eq. (15), relating  $E_S$  to  $m_B$ , which Gutenberg measured in a wide range of periods less than 20 s.

$K$  was supposed to be an estimate of  $\log E_S$ , and therefore should have been determined from the  $(A/T)$  spectrum. However, because of difficulties in conducting proper spectral analyses and integrating analog records in the past, all  $K$  formulations have been based on measuring

only  $A_{max}$ . Gutenberg and Richter (1956) realized that the body-wave scale would yield stable magnitude estimates only by normalizing the  $A_{max}$  value in the P-wave train by its period,  $T$ , which varied in a fairly wide range between some 2 s and 20 s even in records from the limited broadband responses of the medium-period seismographs of that time. Now, modern force-feedback broadband sensors have direct velocity proportional responses at least in the range between about 0.05 and 40 s, or wider, and allow the direct measurement in the entire P- or S-wave train, of the maximum velocity,  $V_{max}$ , which is related to the maximum seismic energy released by the seismic source at the corner frequency of its displacement spectrum (see Bormann, 2011). Thus, we can expect that the single amplitude magnitude

$$mB\_BB = \log (V_{max}/2\pi) + Q(h, \Delta), \quad (18)$$

where  $Q(h, \Delta)$  is the empirically determined Gutenberg and Richter (1956) calibration function, which depends on focal depth,  $h$ , and distance,  $\Delta$ .  $Q(h, \Delta)$  is available in tabulated and diagram form (see DS 3.1) and accounts for the cumulative effects of the diverse, and theoretically not yet sufficiently well known or tractable in detail influences of wave propagation. Thus,  $mB$  is, in fact, a reasonably good estimator for  $E_S$ . This has been confirmed by Di Giacomo, Saul and Bormann (see Bormann, 2011, and Figure 10).

**Figure 10** The relationship between automatically determined values of  $mB$ , equivalent to standard  $mB\_BB$ , and  $Me$ , according to procedures developed at the GFZ German Research Centre for Geosciences by Bormann and Saul (2008) and Di Giacomo et al. (2010). The dashed line is the 1:1 relationship and the solid line the orthogonal regression relation (19). (Figure by courtesy of D. Di Giacomo, 2011).

In the range  $5.5 < mB\_BB < 8.5$  the data in Figure 10 satisfy the following orthogonal relationship between  $mB\_BB$  and the energy magnitude  $Me = (\log E_S - 4.4)/1.5$ :

$$mB\_BB = 0.79 Me + 1.58. \quad (19)$$

Eq. (19) permits the estimation of  $M_e$  (and thus  $E_S$ ) by using very simple and easily to automate  $mB\_BB$  measurements (see Bormann and Saul, 2008) with a standard deviation  $\sigma = 0.18$  magnitude units, about the best average of direct  $M_e$  measurements. This “error” corresponds to an approximately 95% ( $2\sigma$ ) uncertainty in  $E_S$  estimates by a factor of less than 4, which is close to the factor of 2-3 given by Kanamori and Brodsky (2004) for  $E_S$  estimates via the integration of very good broadband seismic data.

Choy and Boatwright (1995) and Boatwright et al. (2002) suggested a method of calculating energy magnitude,  $M_e$ , based on broadband digital data, which has been applied by the U. S. Geological Survey. Therefore, we have attempted orthogonal regressions between  $K$  and  $M_e$  from the U. S. Geological Survey database for a limited number of regions in which data were available (see Table 1) using the same regression method as in Rautian et al. (2007). As noted above, in most cases, the number of events is small ( $< 5$ ), because  $M_e$  is calculated only for larger events (generally  $M_e > 5.5$ ) and  $K$  for smaller local and regional events (generally  $K < 14$ ). Only for the region of Kamchatka enough data have been available to plot  $K$  as a function of  $M_e$ (USGS) (see Figure 11). Despite the large data scatter, the agreement between the orthogonal  $K$ - $M_e$  regression relationship and the  $\log E_S$ - $M_e$  relationship by Choy is surprisingly good, for constant  $M_e$  being within 0.15 to 0.25 units of  $K$ , i.e., just a factor of 1.4 to 1.8 larger in  $E_S$  than from the teleseismic estimate, or, for equal  $K$ , about 0.1 to 0.2 m.u. smaller in related  $M_e$  as compared with the Choy  $\log E_S$ - $M_e$  relationship.

**Figure 11** Orthogonal regression relationship between  $K$  measured for Kamchatka earthquakes and the related teleseismic  $E_S$  - $M_e$ (USGS) relationship.

For other regions, with much less data, the relationships between  $K$  and  $M_e$  are so far less clear and more variable, also with respect to level differences. Central Asia data are the most varied and the regression is biased by a series of low  $M_e$ , but relatively high  $K$ , events (see Table 1). This may hint to rather high-frequency waves radiated from high stress drop earthquakes, which are not well covered by teleseismic observations.. As the data are

concentrated in a narrow range around  $M_e = 5.5-6.0$  and  $K = 14-15$ , this regression has a very low correlation coefficient. Other relationships are more stable, e.g., for the Kurile Islands and the Caucasus, yielding for  $K$  values between 12 and 15.5  $M_e$  estimates that differ  $-0.1$  to  $+0.6$  m.u. from the values derived via the Choy relationship  $M_e = (\log E_s - 4.4)/1.5$ . The latter (for derivation see IS 3.5 and Bormann and Di Giacomo, 2011) can be written in terms of  $K$  as.

$$M_e = 0.667 K - 2.933 = 6.40 + 0.667 (K-14). \quad (20)$$

For magnitudes below 5.5, however, global  $M_e$  is rarely measured because of the small signal-to-noise ratio of  $P$  waves in teleseismic broadband records as well as the difficulties in including frequencies higher than 2 Hz into the complex model calculations.

In their conclusions, Rautian et al. (2007) correctly state that currently used methods for estimating seismic energy and energy magnitude,  $M_e$ , that are based on global models, commonly make simplified theoretical assumptions with respect to Earth structure, attenuation, scattering, site amplification, source radiation pattern, and/or other local or regional geologic factors that preclude their use at non-teleseismic distances.. Especially for small earthquakes recorded at local and regional distances, no easy practical and reliable methodology is currently available. On the other hand, although  $K$  is “ideologically” an energy scale, its practical implementation and use so far is more of a magnitude-like nature, with  $K$  being associated with energy only by correlation (Kondorskaya et. al., 1981). More truly energy-related  $K$  scales would require the consistent measurement of maximum ground motion velocity instead of displacement.

Despite the drawback of current  $K$  scales, the agreement in trend and level of the relationship between the (A/T) derived  $K$  values for earthquakes in Kamchatka (see Figure 5) and teleseismic  $M_e$ (USGS) is very promising. It lets us expect that a  $K$ -type procedure could be developed, which allows to estimate  $E_s$  and  $M_e$  for large numbers of local and regional earthquakes sufficiently reliably in a similarly simple, interactive or easy to automate way as via teleseismic  $mB_{BB}$ . Therefore, we recommend to further develop the  $K$  class system for events with magnitudes below 6, down to magnitudes of about 2, which are recordable with good signal-to-noise ratio at regional and local distances with standardized high-frequency responses. They should have a velocity-proportional pass-band of not less than about 5 octaves relative bandwidth, covering the frequency range between about 0.4 to 10-20 Hz). This would allow to measure in this frequency range directly the largest event velocity amplitudes. This eases both the derivation of local energy-related  $K$  calibration functions as well as later routine  $K$  measurements for estimating  $E_s$  and  $M_e$  of local earthquakes.

On the other hand, we realize from Figure 7 that the orthogonal regression relationships between  $K$  and teleseismic  $m_b$ , respectively  $M_s$  for earthquakes in the Russian subduction zone environments of Kamchatka, Kurile Islands and Sakhalin differ systematically, partially depending on  $K$ , from those derived for other intra-continental regions in FSU states. The differences in  $M_s$  (for equal  $K$ ) reach up to one and for  $m_b$  up to two magnitude units. This is not acceptable and hints, as mentioned already above for Kamchatka, to significant differences in the absolute calibration of the various regional  $K$  scales. Thus there is an urgent need to develop standards for both calibration in continental (shallow earthquakes) and subduction zone environments (with also deep and intermediate depth earthquakes) which yield  $K$  data that are really compatible in a wide range of  $K$  between the different seismotectonic environments and for larger events also with teleseismic  $M_e$  data.

Although there is no more need to measure period specifically for deriving the ground motion velocity, local records in a wide range of magnitudes and from different seismotectonic settings are likely to show a great variability of frequencies at which  $V_{max}$  is measured. The higher the measured frequencies the more the heterogeneity of the Earth medium and of the surface topography at local and regional scale will impact the attenuation effects. They may have to be compensated for by frequency-dependent and maybe even source–distance and azimuth-dependent local and regional calibration functions.

To derive and use such calibration functions goes well beyond traditional K formulas and their application. It will require years of careful and complex empirical data collection and analysis. However, digital data recording, filtering and processing in a standardized way eases this task. Yet, for assuring the better compatibility of future K estimates the new calibration functions have to be scaled so that they agree with original definitions and values at a suitable reference distance, in a similar way as regional Ml calibration functions in other countries have to be scaled to the standard Southern California Ml calibration function (see DS 3.1 and IS 3.3) in order to make them mutually compatible. This degree of compatibility has obviously not yet been achieved with respect to the various regional K-scales currently in use. E.g., in Figure 9, most of the difference between KF68 and KSol has no seismological reason. Rather, it is due to an error in calculating the absolute level of the  $(A_{max}/T)(\Delta, h=40\text{km})$  curve of Fedotov (1963). This makes the K-Sol values by 0.6 units lower than they should be (see Fedotov, 1972, p63). Moreover, the slight differences in slope of these two curves are most likely due to the difference of seismometer periods used, which are 0.7 s for KSol vs. 1.2 s for KF68. Minor differences between the regional K-scales may also originate from different assumptions made by the scale authors on the input parameters used in calculating the wave energy density on the reference sphere, e.g., Fedotov (1972) used  $v_s = 3 \text{ km/s}$ , whereas Rautian used  $v_s = 3.5 \text{ km/s}$ . Such details need to be checked and agreed upon in order to assure an unambiguous absolute calibration as well as standard (simulated) instrument responses and measurement procedures in order to assure interregional K-value compatibility. Only then it will be possible to interpret differences in measurement values that are beyond the range of measurement errors in seismological terms only.

Although most of the seismic energy is radiated in the S-wave group, teleseismic procedures for estimating  $E_s$  generally use the first arriving P waves. The reason is that S-waves from strong earthquakes with large rupture durations of several 10 seconds or even minutes are often superimposed by later secondary, phases. This may bias the results of full waveform integrations in a wide range of periods and rupture durations. Moreover, theoretical corrections for propagation and attenuation effects in a wide range of periods are more difficult to account for S waves than for P waves. But these objections against the use of  $V_{Smax}$  instead of  $V_{Pmax}$  are less relevant for the analysis of weak earthquakes in the regional and local distance range. Earthquakes with magnitudes below 6 have average rupture durations of less than 6 s. Recorded at distances typically less than 1000 km, they have clearly developed distinct later Sg/Lg groups that are well separated in time from the earlier and usually much weaker P-wave phases. This eases significantly proper phase identification and parameter measurement both in automatic and interactive modes.

Finally, another approach, considered by Rautian et al. (2007) to be the most appropriate way to get seismic energy along with seismic moment, apparent stress, etc., is to use the later part of the coda for source spectral estimation (Rautian and Khalturin, 1978). This method had been originally developed for analog records with multi-bandpass filtering and could easily be

adapted as well for digital instrumentation and processing techniques now available. A certain step in this direction is the routine use of short-period coda-class Kc on Kamchatka mentioned above.

## Acknowledgments

We thank Tatyana G. Rautian for extensive help in clarifying various points in the development and calibration of the original K-class scale. Anthony Kendall provided the K to Me correlations and Tea Godoladze assisted in obtaining information on the use of K in the FSU. Thanks go also to George Choy for his careful review and encouraging assessment. This research was supported, in part, by Department of Energy contracts DE-FC03-02SF22490, DE-FC52-2004NA25540 and DE-AC52-09NA29323 to Michigan State University.
